Brief Contents

Volume I

6XXX Alloys: Chemical Composition and Heat Treatment	1	Corrosion-Induced Hydrogen Embrittlement in AA2024	454
Additive Manufacturing of Aluminum Alloys	15	Creation of Master Alloys for Aluminum	468
Aerospace Fasteners: Use in Structural Applications	30	The Crystallography of Aluminum and Its Alloys	488
Aircraft Structural Integrity: Corrosion Effects	46	Defects in Aluminum Alloy Castings	587
Al-Mg-Si: Microstructural Analysis	60	Design of Aluminum Rolling Processes for Foil, Sheet, and Plate	593
Analytical Techniques for Aluminum	74	Design of Forming Processes: Sheet Metal Forming	633
Anisotropic Yield Criteria for Aluminum Alloy Sheets	93	Designing for Aluminum	655
Anodic Oxides: Applications and Trends in Nanofabrication	107	Designing with Aluminum Alloys	674
Arc-Welding: Lithium-Containing Aluminum Alloys	130	Die Casting Process Design	702
As-Cast Grain Size of Aluminum Alloys Refined by Al-Ti-B Master Alloys	135	Diesel Engine: Applications of Aluminum Alloys	743
Atom Probe Characterization of Nanoscale Precipitates in Aluminum Alloys	146	Diffusion Bonding of A2017 Aluminum Alloys	763
Bayer Process	163	Dispersoid Precipitation in Aluminum Alloys	770
Brazing Aluminum in Low Vacuum	168	Ductility–Fatigue Life Relationships in Aluminum Alloy Castings: Role of Structural Quality	778
Brazing of Aluminum Alloys	171	Electrical Conductivity of Aluminum Alloy A2011	784
Bulk Metallic Glasses: Aluminum-Based	183	Electrical Resistivity of Al-Cast Alloys in the Range of Solidification	793
Calcium-Containing Aluminum Alloys	192	Electrochemical Study of Potassium Fluoride in a Cryolite-Aluminum Oxide Molten Salt	801
Carbothermic Reduction Methods for Alumina	207	Electrodeposition of Aluminum in Ionic Liquids	808
Cast Al-Si-Cu Alloys: Effect of Modification on Thermal and Electrical Conductivities	220	Electron Backscatter Diffraction	823
Casting Designs	227	Electron Beam Welding of Aluminum Alloys	859
Castings	248	Electron-Beam Welding of Thick Components of Steels, Aluminum, and Titanium Alloys	870
Castings: Ten Rules for Good Castings	275	Entrainment Defects	873
Chemical Milling of Aluminum	280	Extractive Metallurgy of Aluminum	893
Computer Vision for Fault Detection in Aluminum Castings	332	Extrudable Al-Si-Mg Alloys: Simulation of Microsegregation and Homogenization	919
Control Principle of Thermal Spray Process	378	Extrusion	931
Corrosion and Wear Protection through Micro Arc Oxidation Coatings in Aluminum and Its Alloys	386	Fatigue Endurance under Torsion Testing: 6061-T6 and 6063-T5 Aluminum Alloys	992
Corrosion Inhibitors: Effect on Aluminum Alloys	400	Fatigue Lifetime Improvement of Aluminum Alloys	1000
Corrosion of Aluminum and Its Alloys	410	Field Trials of Aerospace Fasteners in Mechanical and Structural Applications	1007
Corrosion Protective Coatings: Fabrication of Sputtered CeO₂-La₂O₃ and La₂O₃-CeO₂ Bilayers	434	Forging	1022

Volume I (cont'd.)

Friction Stir Processing: Effect on Microstructure and Mechanical Properties in Cast Aluminum Alloys	1037
Friction Welding of Al ₂ O ₃ P/6061 Aluminum Alloy Composite to 5052 Aluminum Alloy	1049
Grain Refinement and Strengthening of Aluminum Alloys: Cold Severe Plastic Deformation Model	1054
Grain Refinement of Cast Aluminum by Heterogeneous Nucleation Sites	1069
Graphene-Reinforced Aluminum Matrix Nanocomposites: Structure and Properties	1085
Hall–Heroult Process	1099
Hall–Petch Relationship in Aluminum and Aluminum Alloys	1104
Hardening, Annealing, and Aging	1123
Hardness–Yield Strength Relationships in Al–Zn–Mg(–Cu) Alloys	1149
Heat-Treatable Aluminum Alloys: Three-Point Bending	1155
High-Pressure Die-Cast AlSi ₉ Cu ₃ (Fe) Alloys: Models for Casting Defects and Mechanical Properties	1162
High-Speed Computer Tomography: Pressure Die Casting	1173
Hipping Evaluation in Cast Aluminum Alloys: Quality Index-Based Approach	1186
Early History of Aluminum Metallurgy	1194
Homogeneous Modifier-Treated AlSi ₁₀ Mg Alloy: Microstructure and Mechanical Properties	1206
Honeycomb Composite Structures of Aluminum: Aerospace Applications	1213
Hot Stamping of Complex-Shaped High-Strength Aluminum Components	1244
Hot Tear Nucleation During Solidification of Aluminum and Its Alloys	1263
Hypoeutectic Al–Fe Alloys: Formation and Characterization of Intermetallics by Dissolution of the Al Matrix	1270
Image Processing for Fault Detection in Aluminum Castings	1287
Intermetallics of Aluminum	1312
Introduction to Aluminum	1327
Ionic Liquids in Surface Protection of Aluminum and Its Alloys	1346
Iron: Removal from Aluminum	1356
Machining	1390
Master Alloys for Grain Refinement	1417
Melt Quality Assessment	1430

Melt-Stirring Method: Influence on Ingot Purity During Ohno Continuous Casting	1446
Metal Casting Research: Application to Aluminum Alloy Casting	1456
Metallic Coatings for Brazing Aluminum Alloys	1461

Volume II

Metallography of Aluminum Alloys: Atlas of Microstructures	1465
Metallurgy of Continuous Hot Dip Aluminizing	1486
Metallurgy of Quenching Aluminum Alloys	1511
Microgravity Crystallization for High-Tech Castings	1535
Micromachining of Aluminum Alloys	1557
Microstructural Changes During Annealing of Aluminum Alloy: Modeling	1592
Microstructural Evolution During Solution Treatment of ADC12 (A383) Alloy Die Castings	1605
Microstructure and Microhardness of AlZnMnMg Alloys during Heat Treatment	1613
Microstructure and Properties of Friction Stir Welded Aluminum Alloys	1621
Microstructure and Yield Strength Evolution of Aluminum Alloys	1627
Microstructure Imaging, Precipitation Formation and Mechanical Properties: Al–Li and Al–Mg–Zn Alloys	1648
Microstructure of Al–Cu, Al–Zn, Al–Ag–Zn, and Al–Zn–Mg Alloys	1659
Microstructure of Aluminum Alloys: Effect of Hardening Conditions	1675
MIG Welding of Aluminum Alloys	1685
Molten Aluminum: Inductive Technique for Electrical Conductivity Measurements	1689
Molten Metal Processing	1698
Nanocomposites with Aluminum Matrix: Preparation and Properties	1725
Nanoparticle Aluminum Preparation	1738
Nanostructured Aluminum Films: Deep Ultraviolet Absorption from Glancing Angle Physical Vapor Deposition	1763
Nanostructured Ni/Al ₂ O ₃ Interlayer: Transient Liquid Phase Diffusion Bonding of Al6061-MMC	1767

Nodular Silicon Al–(12–30)% Si Alloys:		
Microstructure, Mechanical Properties and Fracture Behaviors	1779	
Non-Heat Treatable Al-Alloys: Development of Intermetallic Particles during Solidification and Homogenization	1797	
Open-Cell Foam Metal Production and Characterization by Aluminum Solid Mold Investment Casting	1816	
Optical Microstructures of Aluminum Alloys	1822	
Plasma Electrolytic Oxidation (PEO) Coatings on Aluminum Alloys: Kinetics and Formation Mechanism	1903	
Plasma Surface Treatment: Effects on Mechanical and Corrosion Protection Properties of Hybrid Sol–Gel Coatings	1922	
Plastic Flow of Aluminum in Explosive Welding	1929	
Polyphase Eutectics of Aluminum Alloys: Effect of Phase Composition	1932	
Porosity Development and Modification in Al-Si Alloys: Effect of P and Sr	1951	
Porosity in Aluminum Alloy Castings	1959	
Porosity in Aluminum Welds	1973	
Powder Metallurgy Aluminum Alloys: Structure and Porosity	1977	
Precipitation in AA2195 by Atom Probe Tomography and Transmission Electron Microscopy	1996	
Precipitation in Al–Mg–Si Alloys: Modeling	2005	
Production Levels of Bauxite and Aluminum: Global Historical Survey (1850–2015)	2013	
Production Methods for Aluminum: Alternative	2040	
Properties of Pure Aluminum	2060	
Pulsed TIG Welding of Al–SiC Composite: Welding Parameter Optimization	2090	
Pulsed TIG Welding of Aluminum	2142	
Quality Parameters for High-Pressure Diecastings	2153	
Quench Factor Analysis: An Overview	2173	
Quench Sensitivity and Continuous Cooling Precipitation Diagrams	2189	
Quench Sensitivity of Aluminum Alloys	2218	
Quenching of Aluminum Alloys	2224	
Quenching of Aluminum Solid Cylinder: Numerical Study	2286	
Reaction Kinetics during Molten Aluminum Refining Using Electron Backscatter Diffraction	2294	
Recrystallization and Grain Growth	2314	
Recycling of Aluminum	2341	
Recycling of EN AW 2011 Aluminum Chips without Remelting	2361	
Residual Stress during Stamping-Forging of 2024 Aluminum Alloy Sheet	2370	
Retrogression and Re-aging Heat Treatment: AA7XXX Aluminum Alloys	2379	
Rheoprocessing of Semisolid Aluminum Alloys	2395	
Rolling of Aluminum	2407	
SEM Microstructures and Fractographs of Aluminum Alloys	2427	
Shielding Gas: Performance Improvement of MIG and TIG Welding of Aluminum Alloys	2471	
Sintering Behavior: Al–SiC Compacts in Different Atmospheres	2483	
Smelting of Aluminum	2490	
Solidification of Aluminum Alloy Weld Metal	2510	
Steel: Aluminum Coatings	2519	
Stellite Superalloy Powder Deposition on 7075 Aluminum Alloy	2523	
Strain Rate Sensitivity of Commercial Aluminum Alloys	2528	
Strength and Intergranular Corrosion of Aluminum Alloys: Effect of Cooling Rate	2543	
Superplastic Forming	2549	
Surface Chemistry of Adhesion to Aluminum	2578	
Surface Modification of Aluminum and Its Alloys Using Conversion Coatings	2589	
Texture–Property Relationships in Aluminum Alloys: Simulations and Experiments	2599	
Thermal Analysis of Aluminum Alloys	2625	
Thermal Analysis of Aluminum Alloys	2649	
Thermal Spray Coatings: Aluminum Alloy Protection	2680	
Thin Aluminum Sheets: Continuous Casting and Rolling	2696	
Transmission Electron Micrographs of Aluminum Alloys	2706	
Tube Bending Forming Technologies: Advances and Trends	2732	
Twist Compression Welding of Aluminum	2751	
Uphill Quenching of Aluminum Alloys	2757	
Vacuum Carbothermic Reduction of Alumina	2771	
Wear Behavior of Aluminum Alloys at Slow Sliding Speeds	2778	
Weldability: Effect of Alloying Element Sc, Mn, and Zr on Alloys of the Al-Mg-Sc-Mn-Zr System	2789	
Weldable Aluminum Alloys in Aerospace and Transportation	2792	
Welding aluminium Die Castings	2829	

Welding Parameters for Aluminum Alloys	2835	X-Ray Diffraction Analysis of the	
Welding Technology: Gas Chromatography in . . .	2856	Microstructure of Precipitating Aluminum-	
Welding: Particulate and Gaseous Emissions. . .	2860	Based Alloys.	2883
Wrought Aluminum Alloy: Reinforcement,			
Alloy Addition, and Deformation Effects on			
Mechanical Responses	2871

Contents

<i>Contributors</i>	xi
<i>Preface</i>	xxxi
<i>About the Editors</i>	xxxiii

Volume I

6XXX Alloys: Chemical Composition and Heat Treatment / Grażyna Mrówka-Nowotnik	1
Additive Manufacturing of Aluminum Alloys / Sriram Praneeth Isanaka, Sreekar Karnati, and Frank Liou	15
Aerospace Fasteners: Use in Structural Applications / George Nadim Melhem	30
Aircraft Structural Integrity: Corrosion Effects / Bruce Crawford, Chris Loader, and Timothy J. Harrison	46
Al-Mg-Si: Microstructural Analysis / Marcello Cabibbo	60
Analytical Techniques for Aluminum / Alexis Deschamps	74
Anisotropic Yield Criteria for Aluminum Alloy Sheets / Dorel Banabic, Dan Sorin Comsa, and Tudor Balan	93
Anodic Oxides: Applications and Trends in Nanofabrication / W.J. Stepniowski	107
Arc-Welding: Lithium-Containing Aluminum Alloys / V. I. Ryazantsev and V. A. Fedoseev	130
As-Cast Grain Size of Aluminum Alloys Refined by Al-Ti-B Master Alloys / Mark Easton, David St John, and Arvind Prasad	135
Atom Probe Characterization of Nanoscale Precipitates in Aluminum Alloys / K. Hono	146
Bayer Process / Diego Lozano, Gabriela M. Martínez-Cázares, and Miguel Bocanegra	163
Brazing Aluminum in Low Vacuum / B. N. Perevezentsev, N. M. Sokolova, and G. A. Telitsyna	168
Brazing of Aluminum Alloys / Y. Sugiyama	171
Bulk Metallic Glasses: Aluminum-Based / B.J. Yang, J.H. Yao, J.Q. Wang, Y.S. Chao, and E. Ma	183
Calcium-Containing Aluminum Alloys / Torgom Akopyan, Nikolay Belov, and Evgenia Naumova	192
Carbothermic Reduction Methods for Alumina / Efthymios Balomenos and Dimitrios Gerogiorgis	207
Cast Al-Si-Cu Alloys: Effect of Modification on Thermal and Electrical Conductivities / Carlos Huitrón, Eduardo Valdés, Salvador Valtierra, and Rafael Colás	220
Casting Designs / Henry W. Stoll	227
Castings / Rafael Colás, Eulogio Velasco, and Salvador Valtierra	248
Castings: Ten Rules for Good Castings / John Campbell	275
Chemical Milling of Aluminum / Bruce M. Griffin	280
Computer Vision for Fault Detection in Aluminum Castings / Domingo Mery	332
Control Principle of Thermal Spray Process / Masahiro Fukumoto	378
Corrosion and Wear Protection through Micro Arc Oxidation Coatings in Aluminum and Its Alloys / L. Rama Krishna and G. Sundararajan	386
Corrosion Inhibitors: Effect on Aluminum Alloys / Feyisayo Victoria Adams, Mbali Mokgatla, Abubakar Ishak, Chukwuma Valentine Onwujiuba, Pwafureino Reuel Moses, and Utseoritselaju Okorodudu	400
Corrosion of Aluminum and Its Alloys / T. David Burleigh	410
Corrosion Protective Coatings: Fabrication of Sputtered CeO₂-La₂O₃ and La₂O₃-CeO₂ Bilayers / Miguel Antonio Dominguez-Crespo, Silvia Brachetti-Sibaja, Aide Torres-Huerta, Edgar Onofre, Ana Lopez-Oyama, and Sandra Rodil	434

Volume I (cont'd.)

Corrosion-Induced Hydrogen Embrittlement in AA2024 / <i>G.N. Haidemenopoulos and Helen J. Kamoutsi</i>	454
Creation of Master Alloys for Aluminum / <i>Michael M. Gasik and Vladislav I. Mazur</i>	468
The Crystallography of Aluminum and Its Alloys / <i>Philip N.H. Nakashima</i>	488
Defects in Aluminum Alloy Castings / <i>John Campbell</i>	587
Design of Aluminum Rolling Processes for Foil, Sheet, and Plate / <i>Julian H. Driver and Olaf Engler</i>	593
Design of Forming Processes: Sheet Metal Forming / <i>T. Wanheim</i>	633
Designing for Aluminum / <i>Howard A. Kuhn</i>	655
Designing with Aluminum Alloys / <i>Nack J. Kim</i>	674
Die Casting Process Design / <i>Frank E. Goodwin</i>	702
Diesel Engine: Applications of Aluminum Alloys / <i>Mihriban Pekguleryuz, Erol Ozbakir, and Amir Rezaei Farkoosh</i>	743
Diffusion Bonding of A2017 Aluminum Alloys / <i>T. Latouche, M. Cailler, B. Sander, and S.K. Marya</i>	763
Dispersoid Precipitation in Aluminum Alloys / <i>Joseph D. Robson</i>	770
Ductility–Fatigue Life Relationships in Aluminum Alloy Castings: Role of Structural Quality / <i>Murat Tiryakioğlu and Hüseyin Özdeş</i>	778
Electrical Conductivity of Aluminum Alloy A2011 / <i>Sayavur Bakhtiyarov and Ruel Overfelt</i>	784
Electrical Resistivity of Al-Cast Alloys in the Range of Solidification / <i>Mitja Petric, Jožef Medved, Sebastjan Kastelic, Maja Vončina, and Primož Mrvar</i>	793
Electrochemical Study of Potassium Fluoride in a Cryolite-Aluminum Oxide Molten Salt / <i>Shaohu Tao, Jianping Peng, Yuezhong Di, Kejia Liu, Kun Zhao, and Naixiang Feng</i>	801
Electrodeposition of Aluminum in Ionic Liquids / <i>Qian Wang, Suojian Zhang, Xingmei Lu, and Xiangping Zhang</i>	808
Electron Backscatter Diffraction / <i>David P. Field and Mukul Kumar</i>	823
Electron Beam Welding of Aluminum Alloys / <i>Mohamed Sobih and Zuhair Elseddig</i>	859
Electron-Beam Welding of Thick Components of Steels, Aluminum, and Titanium Alloys / <i>V.N. Martynov, A.S. Khokhlovskii, and A.P. Sliva</i>	870
Entrainment Defects / <i>J. Campbell</i>	873
Extractive Metallurgy of Aluminum / <i>Fathi Habashi</i>	893
Extrudable Al-Si-Mg Alloys: Simulation of Microsegregation and Homogenization / <i>G.N. Haidemenopoulos and Panagiota Sarafoglou</i>	919
Extrusion / <i>Sigurd Stvren and Per Thomas Moe</i>	931
Fatigue Endurance under Torsion Testing: 6061-T6 and 6063-T5 Aluminum Alloys / <i>Jorge L. Avila Ambriz, Erasmo Correa Gómez, Julio C. Verduzco Juárez, Gonzalo M. Dominguez Almaraz, and Aymeric E. Dominguez</i>	992
Fatigue Lifetime Improvement of Aluminum Alloys / <i>Patiphan Juijerm and Berthold Scholtes</i>	1000
Field Trials of Aerospace Fasteners in Mechanical and Structural Applications / <i>George Nadim Melhem, Paul Richard Munroe, Charles Christopher Sorrell, and Alsten Clyde Livingstone</i>	1007
Forging / <i>Kichitaro Shinozaki and Kazuho Miyamoto</i>	1022
Friction Stir Processing: Effect on Microstructure and Mechanical Properties in Cast Aluminum Alloys / <i>Murat Tiryakioğlu and Nelson Netto</i>	1037
Friction Welding of Al₂O₃P/6061 Aluminum Alloy Composite to 5052 Aluminum Alloy / <i>K. Kato and H. Tokisue</i>	1049
Grain Refinement and Strengthening of Aluminum Alloys: Cold Severe Plastic Deformation Model / <i>Xiao Guang Qiao, Nong Gao, and Marco Starink</i>	1054
Grain Refinement of Cast Aluminum by Heterogeneous Nucleation Sites / <i>Yoshimi Watanabe and Hisashi Sato</i>	1069

Graphene-Reinforced Aluminum Matrix Nanocomposites: Structure and Properties / S.J. Yan, Xiang Chen, Qihu Hong, Nan Wang, Xiuhui Li, Shuangzan Zhao, Wenzheng Nan, Xiaoyan Zhang, Shenglong Dai, and Zuoming Lin	1085
Hall–Heroult Process / Gabriela M. Martínez-Cázares and Diego Lozano	1099
Hall–Petch Relationship in Aluminum and Aluminum Alloys / Ronald W. Armstrong	1104
Hardening, Annealing, and Aging / Laurens Ketgerman and D. Eskin	1123
Hardness–Yield Strength Relationships in Al–Zn–Mg(–Cu) Alloys / Murat Tiryakioglu	1149
Heat-Treatable Aluminum Alloys: Three-Point Bending / Ida Westermann and Gaute Gruben	1155
High-Pressure Die-Cast AlSi₅Cu₃(Fe) Alloys: Models for Casting Defects and Mechanical Properties / Giulio Timelli	1162
High-Speed Computer Tomography: Pressure Die Casting / Christian Heikel and Eberhard Ambos	1173
Hipping Evaluation in Cast Aluminum Alloys: Quality Index-Based Approach / M. Nageswara Rao, G. Dhineshbabu, and Prateek Sibal	1186
Early History of Aluminum Metallurgy / Norman C. Craig	1194
Homogeneous Modifier-Treated AlSi₁₀Mg Alloy: Microstructure and Mechanical Properties / Tomasz Lipiński	1206
Honeycomb Composite Structures of Aluminum: Aerospace Applications / D. L. Majid, Nor Hafizah Manan, and Yee Ling Chok	1213
Hot Stamping of Complex-Shaped High-Strength Aluminum Components / Liliang Wang, Jun Liu, and Jianguo Lin	1244
Hot Tear Nucleation During Solidification of Aluminum and Its Alloys / Murat Tiryakioglu and Pedram Yousefian	1263
Hypoeutectic Al–Fe Alloys: Formation and Characterization of Intermetallics by Dissolution of the Al Matrix / Amauri Garcia, Pedro Goulart, Felipe Bertelli, Jose Spinelli, and Noe Cheung	1270
Image Processing for Fault Detection in Aluminum Castings / Domingo Mery, Dieter Filbert, and Thomas Jaeger	1287
Intermetallics of Aluminum / Georg Frommeyer and Sven Knippscheer	1312
Introduction to Aluminum / Alexey Sverdlin	1327
Ionic Liquids in Surface Protection of Aluminum and Its Alloys / Joaquin Arias-Pardilla, Tulia Espinosa, José Sanes, Ana Eva Jiménez, Ginés Martínez-Nicolás, and María Dolores Bermúdez	1346
Iron: Removal from Aluminum / Lifeng Zhang, Jianwei Gao, Lucas Nana Wiredu Damoah, and David G. Robertson	1356
Machining / I. S. Jawahir and A. K. Balaji	1390
Master Alloys for Grain Refinement / Xiaoming Wang	1417
Melt Quality Assessment / Derya Dispinar	1430
Melt-Stirring Method: Influence on Ingot Purity During Ohno Continuous Casting / Simbarashe Fashu, Lynette Mudzingwa, Aaron Mukuya, Macdonald Tozvireva, and Rajwali Khan	1446
Metal Casting Research: Application to Aluminum Alloy Casting / Murat Tiryakioğlu and J. Campbell	1456
Metallic Coatings for Brazing Aluminum Alloys / A. A. Suslov	1461

Volume II

Metallography of Aluminum Alloys: Atlas of Microstructures / S.V.S. Narayana Murty, Sushant K. Manwatkar, and P. Ramesh Narayanan	1465
Metallurgy of Continuous Hot Dip Aluminizing / R. W. Richards, H. Clarke, R. D. Jones, and P. D. Clements	1486

Volume II (cont'd.)

Metallurgy of Quenching Aluminum Alloys / <i>Ralph T. Shuey and Murat Tiryakioğlu</i>	1511
Microgravity Crystallization for High-Tech Castings / <i>Hans M. Tensi</i>	1535
Micromachining of Aluminum Alloys / <i>Ann Rumsey and Muhammad Jahan</i>	1557
Microstructural Changes During Annealing of Aluminum Alloy: Modeling / <i>Soheila Shabaniverki and S. Serajzadeh</i>	1592
Microstructural Evolution During Solution Treatment of ADC12 (A383) Alloy Die Castings / <i>Gil-Yong Yeom, Ghasem Eisaabadi Bozchaloei, Hyun-Kyu Lim, Shae Kwang Kim, Young-Ok Yoon, Soong-Keun Hyun, Nelson Netto, and Murat Tiryakioğlu</i>	1605
Microstructure and Microhardness of AlZnMnMg Alloys during Heat Treatment / <i>S. Valdez-Rodríguez, B. Campillo, and J. Islas</i>	1613
Microstructure and Properties of Friction Stir Welded Aluminum Alloys / <i>Izabela Kalemba and Stanisław Dymek</i>	1621
Microstructure and Yield Strength Evolution of Aluminum Alloys / <i>Kai Li, Yong Du, and Min Song</i>	1627
Microstructure Imaging, Precipitation Formation and Mechanical Properties: Al–Li and Al–Mg–Zn Alloys / <i>Wilfried Wunderlich, Janos Lendvai, and Hans-Joachim Gudladt</i>	1648
Microstructure of Al–Cu, Al–Zn, Al–Ag–Zn, and Al–Zn–Mg Alloys / <i>Stanko Popović and Željko Skoko</i>	1659
Microstructure of Aluminum Alloys: Effect of Hardening Conditions / <i>Hülya Demirören</i>	1675
MIG Welding of Aluminum Alloys / <i>K. Yasuda</i>	1685
Molten Aluminum: Inductive Technique for Electrical Conductivity Measurements / <i>Sayavur Bakhtiyarov and Ruel Overfelt</i>	1689
Molten Metal Processing / <i>Ryotatsu Otsuka</i>	1698
Nanocomposites with Aluminum Matrix: Preparation and Properties / <i>Jacopo Fiocchi, Riccardo Casati, and Maurizio Vedani</i>	1725
Nanoparticle Aluminum Preparation / <i>Soma Venugopal Rao, Krishnamurthi Muralidharan, and Anuj A. Vargeese</i>	1738
Nanostructured Aluminum Films: Deep Ultraviolet Absorption from Glancing Angle Physical Vapor Deposition / <i>Stephen Stagon and Ryan Scherzer</i>	1763
Nanostructured Ni/Al₂O₃ Interlayer: Transient Liquid Phase Diffusion Bonding of Al6061-MMC / <i>Kavian Cooke and Tahir Khan</i>	1767
Nodular Silicon Al–(12–30) % Si Alloys: Microstructure, Mechanical Properties and Fracture Behaviors / <i>Ruyao Wang and Wei Hua Lu</i>	1779
Non-Heat Treatable Al-Alloys: Development of Intermetallic Particles during Solidification and Homogenization / <i>Olaf Engler, Katrin Kuhnke, and Jochen Hasenclever</i>	1797
Open-Cell Foam Metal Production and Characterization by Aluminum Solid Mold Investment Casting / <i>Kerem Altug Guler</i>	1816
Optical Microstructures of Aluminum Alloys / <i>S.V.S. Narayana Murty, Sushant Manwatkar, and Ramesh Narayanan</i>	1822
Plasma Electrolytic Oxidation (PEO) Coatings on Aluminum Alloys: Kinetics and Formation Mechanism / <i>Alex Lugovskoy and Lyubov Snizhko</i>	1903
Plasma Surface Treatment: Effects on Mechanical and Corrosion Protection Properties of Hybrid Sol–Gel Coatings / <i>R. Subasri</i>	1922
Plastic Flow of Aluminum in Explosive Welding / <i>V. G. Petushkov, M. I. Zotov, and L. D. Dobrushin</i>	1929
Polyphase Eutectics of Aluminum Alloys: Effect of Phase Composition / <i>Malgorzata Warmuzek</i>	1932
Porosity Development and Modification in Al–Si Alloys: Effect of P and Sr / <i>J. Campbell and Murat Tiryakioğlu</i>	1951

Porosity in Aluminum Alloy Castings / Lenka Kuchariková, Eva Tillová, Juraj Belan, and Milan Uhrčík	1959
Porosity in Aluminum Welds / M. Mazur	1973
Powder Metallurgy Aluminum Alloys: Structure and Porosity / Will Judge and Georges Kipourous	1977
Precipitation in AA2195 by Atom Probe Tomography and Transmission Electron Microscopy / Muna Khushaim	1996
Precipitation in Al–Mg–Si Alloys: Modeling / Abbas Bahrami, Maryam Yazdan Mehr, and Seyyed Hashem Mousavi Anijdan	2005
Production Levels of Bauxite and Aluminum: Global Historical Survey (1850–2015) / Charles Christopher Sorrell and Pramod Koshy	2013
Production Methods for Aluminum: Alternative / M. A. Rhamdhani, G. A. Brooks, M. A. Dewan, B. J. Monaghan, and L. Prentice	2040
Properties of Pure Aluminum / Alexey Sverdlin	2060
Pulsed TIG Welding of Al–SiC Composite: Welding Parameter Optimization / Sivachidambaram P., Raghuraman Srinivasan, and Venkatraman Ramamoorthy	2090
Pulsed TIG Welding of Aluminum / S. Katoh	2142
Quality Parameters for High-Pressure Diecastings / Roger Lumley	2153
Quench Factor Analysis: An Overview / Rosa L. Simencio Otero, Patricia M. Kavalco, Lauralice C. F. Canale, George E. Totten, and Lemmy Meekisho	2173
Quench Sensitivity and Continuous Cooling Precipitation Diagrams / Olaf Kessler, Benjamin Milkereit, and Christoph Schick	2189
Quench Sensitivity of Aluminum Alloys / Barbara Rivolta and R. Gerosa	2218
Quenching of Aluminum Alloys / Wellington da Silva Mattos, Barbara Rivolta, George Totten, Lemmy Meekisho, and Lauralice Canale	2224
Quenching of Aluminum Solid Cylinder: Numerical Study / Shahriar Jahanian	2286
Reaction Kinetics during Molten Aluminum Refining Using Electron Backscatter Diffraction / Alfredo Flores Valdés, Jesús Torres, and Rocío Ochoa	2294
Recrystallization and Grain Growth / Weimin Mao	2314
Recycling of Aluminum / Jorge Alberto Soares Tenório and Denise Crocce Romano Espinosa	2341
Recycling of EN AW 2011 Aluminum Chips without Remelting / Branimir Lela and Jure Krolo	2361
Residual Stress during Stamping-Forging of 2024 Aluminum Alloy Sheet / Xinyun Wang, Lei Deng, and Jinbo Li	2370
Retrogression and Re-aging Heat Treatment: AA7XXX Aluminum Alloys / V. Anil Kumar, R.K. Gupta, P.V. Venkitakrishnan, and S. Arjun	2379
Rheoprocessing of Semisolid Aluminum Alloys / Sayavur Bakhtiyarov, Dennis Siginer, and Dennis A. Siginer	2395
Rolling of Aluminum / Kai F. Karhausen and Antti S. Korhonen	2407
SEM Microstructures and Fractographs of Aluminum Alloys / S.V.S. Narayana Murty, Sushant K. Manwatkar, and P. Ramesh Narayanan	2427
Shielding Gas: Performance Improvement of MIG and TIG Welding of Aluminum Alloys / J.M. Fortain and S. Gadrey	2471
Sintering Behavior: Al–SiC Compacts in Different Atmospheres / Tadeusz Pieczonka	2483
Smelting of Aluminum / Michael M. Gasik and Michael I. Gasik	2490
Solidification of Aluminum Alloy Weld Metal / S. Ota, K. Asai, and S. Oya	2510
Steel: Aluminum Coatings / Aruna Bahadur	2519
Stellite Superalloy Powder Deposition on 7075 Aluminum Alloy / L. C. Casteletti, A. Lombardi Neto, D. T. de Macedo, L. B. Cruvinel, and George Totten	2523
Strain Rate Sensitivity of Commercial Aluminum Alloys / R.C. Picu	2528

Volume II (cont'd.)

Strength and Intergranular Corrosion of Aluminum Alloys: Effect of Cooling Rate / Patricia Mariane Kavalco, Lauralice Canale, and George Totten	2543
Superplastic Forming / Norman Ridley	2549
Surface Chemistry of Adhesion to Aluminum / Margaret M. Hyland	2578
Surface Modification of Aluminum and Its Alloys Using Conversion Coatings / L. Anicai and Teodor Visan	2589
Texture–Property Relationships in Aluminum Alloys: Simulations and Experiments / Dierk Raabe	2599
Thermal Analysis of Aluminum Alloys / Daniel Larouche	2625
Thermal Analysis of Aluminum Alloys / Consuelo García-Cordovilla and Enrique Louis	2649
Thermal Spray Coatings: Aluminum Alloy Protection / Pitchuka Suresh Babu, D. Srinivasa Rao, Ligamaneni Rama Krishna, Govindan Sundararajan, and Arvind Agarwal	2680
Thin Aluminum Sheets: Continuous Casting and Rolling / Ildiko Peter and Mario Rosso	2696
Transmission Electron Micrographs of Aluminum Alloys / S.V.S. Narayana Murty, Sushant Manwatkar, and Ramesh Narayanan	2706
Tube Bending Forming Technologies: Advances and Trends / Heng Li, He Yang, and Jun Ma ...	2732
Twist Compression Welding of Aluminum / T. Yokota, T. Hashimoto, M. Otsuka, M. Nobutoki, and T. Ueki	2751
Uphill Quenching of Aluminum Alloys / Wellington da Silva Mattos, George Edward Totten, and Lauralice de Campos Franceschini Canale	2757
Vacuum Carbothermic Reduction of Alumina / Martin Halmann, Aldo Steinfeld, Michael Epstein, and Irina Vishnevetsky	2771
Wear Behavior of Aluminum Alloys at Slow Sliding Speeds / M. Ruiz-Andrés, A. Conde, J. de Damborenea, and I. García	2778
Weldability: Effect of Alloying Element Sc, Mn, and Zr on Alloys of the Al-Mg-Sc-Mn-Zr System / V. I. Lukin	2789
Weldable Aluminum Alloys in Aerospace and Transportation / Alexey Sverdlin	2792
Welding aluminium Die Castings / Toyosaku Gonda	2829
Welding Parameters for Aluminum Alloys / Meysam Haghsheenas	2835
Welding Technology: Gas Chromatography in / R. Probst and K. Splitt	2856
Welding: Particulate and Gaseous Emissions / Homer Cole, Seymour Epstein, and Jon Peace ...	2860
Wrought Aluminum Alloy: Reinforcement, Alloy Addition, and Deformation Effects on Mechanical Responses / Samson Oluropo Adeosun, E. I. Akpan, and S. A. Balogun	2871
X-Ray Diffraction Analysis of the Microstructure of Precipitating Aluminum-Based Alloys / E. J. Mittemeijer	2883

Preface

Aluminum is the third most abundant element, after oxygen and silicon, and it constitutes 6% of the earth's crust. It is a relatively soft, lightweight, and it is among the most ductile, and malleable metals. It combines readily with other substance, including: copper, magnesium and silicon, among others leading to the formation of high-strength aluminum alloys of importance in many industries, especially the aerospace and automotive industries.

Ornamental aluminum has reportedly been found in the tomb of Chou-Chu, a military leader in 3rd century China. However, it wasn't specifically identified until 1808 by Humphrey Davy reported its presence in alum. It wasn't until 1825 that Hans Christian Oersted isolated aluminum by heating aluminum chloride with potassium. Friedrich Wöhler subsequently perfected the method in 1827 to obtain pure aluminum for the first time and established many of its properties. In 1886, almost simultaneously, Charles Martin Hall and Paul Lois Toussaint Héroult discovered a commercially important production process in use today by dissolving aluminum oxide in molten cryolite and then extracted the aluminum by electrolysis which is known as the Hall-Héroult process. This process was further improved in 1888 by Karl Bayer who developed a low-cost process for producing aluminum oxide from bauxite. Currently, more aluminum is produced each year than all other non-ferrous metals combined.

In view of their critical importance across many industrial sectors, there is a need to for a comprehensive reference on the production, use and properties of aluminum and its alloys. Currently, there are two excellent references developed for this purpose including the excellent Aluminum Taschenbuch and the Aluminum Handbook. However, as comprehensive as they are, they are still relatively limited in their coverage. There remains the need for even more comprehensive, in-depth, topical, encyclopedic coverage that can be readily expanded as new information becomes available. This was the objective in the development of the *Encyclopedia of Aluminum and Its Alloys* (EAIA).

The organization of the multi-volume EAIA contains articles that provide a thorough overview of topics including extractive metallurgy, casting, forging, coatings, thermal process, joining and micro-structural and property characterization. The articles contained in the peer-reviewed EAIA were contributed by global experts in their areas of specialty. Taken together, the comprehensive coverage of these technologies will be an invaluable authoritative resource to a wide range of users including: metallurgists, material scientists and engineers, process engineers, industrial engineers, students, libraries and others.

It is noteworthy that EAIA will be available both in print and electronic formats, and it will be corrected with the issue of new editions to reflect rapid changes to assure its continued relevance to the industry.

Putting together a reference series of this scope and magnitude has been the product of the contributions of many authors and support functions for which we are particularly indebted and most grateful. We are especially indebted to the Taylor & Francis support staff without which this project could not have been completed. Finally, special acknowledgement to the sacrifice and seemingly eternal patience of our families without which completion of this project would not have been possible.

About the Editors

George E. Totten received his BS and MS degrees from Fairleigh Dickinson University in New Jersey and his Ph.D. from New York University. Dr. Totten is past-president of the International Federation for Heat Treating and Surface Engineering (IFHTSE) and a fellow of ASM International, SAE International, IFHTSE, ASTM International, IFHTSE and he is a Founding Fellow of AMME (World Academy of Materials Manufacturing Engineering). Dr. Totten is a Research Professor at Portland State University, Portland, OR. He is also president of G.E. Totten & Associates LLC, a research and consulting firm specializing in Thermal Processing and Industrial Lubrication problems. Dr. Totten is the author or coauthor (editor) of approximately 750 publications including patents, technical papers, chapters and books. A partial listing of CRC Titles co-edited by Dr. Totten includes: Handbook of Aluminum: Vol. 1 – Physical Metallurgy and Processes, Handbook of Aluminum: Vol. 2 – Alloy Production and materials Manufacturing, Handbook of Mechanical Alloys, Surface Modifications and Mechanisms: Friction, Stress and Reaction Engineering, Mechanical Tribology: Materials, Characterization and Applications, Handbook of Metallurgical Process Design, Analytical Characterization of Aluminum, Steel, and Super-alloys, Steel Heat Treatment Handbook, Second Edition, Quenching Theory and Technology 2nd Edition, and Encyclopedia of Iron, Steel and Their Alloys.

Murat Tiryakioğlu is a Professor of Mechanical Engineering at the University of North Florida. He received his B.S. in Mechanical Engineering from Boğaziçi University (1990), M.S. (1991) and Ph.D. (1993) in Engineering Management from the University of Missouri-Rolla, and another Ph.D. in Metallurgy and Materials. (2002), from the University of Birmingham, England.

Dr. Tiryakioğlu grew up around his family's foundry, which continues to thrive in Istanbul, Turkey. This has led to research interests in process design for high quality castings, aluminum heat treatment modeling and optimization, process-structure-property relationships in metals, statistical modeling and quality and reliability improvement, on which he has written two chapters, published over 100 technical papers, and edited nine books.

Dr. Tiryakioğlu was awarded the inaugural *John Campbell Medal* from the Institute of Cast Metals Engineers (UK), the *Eugene Merchant Outstanding Young Manufacturing Engineer* by the Society of Manufacturing Engineers. He was also selected a *TMS Young Leader* in Light Metals. He is a member of ASM International, TMS and ASQ, and is an *ASQ Certified Quality Engineer*.

Prof. Dr.-Ing. habil. Olaf Kessler finished his Diploma studies in Production Engineering at the University of Bremen, Germany in 1989. Afterwards he started his scientific career at the Foundation Institute for Materials Science, Bremen, Germany under the supervision of Prof. Dr.-Ing. habil. Peter Mayr. He achieved his Doctorate degree as Dr.-Ing. at the University of Bremen in 1995 and his post-doctoral lecture qualification as Dr.-Ing. habil. at the University of Bremen in 2003. Following he established and headed the group of Lightweight Materials at the Foundation Institute for Materials Science, Bremen. Prof. Kessler has been appointed as a full professor for Materials Science at the University of Rostock, Germany in 2007. He is member of the executive committee of the Competence Center for Calorimetry and Thermal Analysis (CALOR) at the University of Rostock, Germany. He has about 20 years of experience in manufacturing, especially heat treatment, as well as microstructure analysis and properties characterization of metals, particularly aluminum alloys.

6XXX Alloys: Chemical Composition and Heat Treatment

Grażyna Mrówka-Nowotnik

Department of Materials Science, Rzeszow University of Technology, Al. Powstańców
Warszawy 12, Rzeszow, podkarpackie, 35-959, Poland

Abstract

Analysis of the influence of chemical composition, crystallization process and heat treatment on the phase constituents' morphology, and mechanical properties and crack resistance of 6xxx Al alloys were conducted. The alloys with low Mg and Si content (6063) in the as-cast state are characterized by presence of Si particles and primary intermetallic phases: α -Al₈Fe₂Si, β -Al₅FeSi, β -Mg₂Si, and α -Al(FeMn)Si. Higher Mg, Si, and Mn content (6005 and 6082) leads to separation of additional phase particles: Al₆Fe, Al₆Mn, and Al₁₂(FeMn)Mg₃Si₆, whereas high Cu content (6061—0.35% and 6066—0.95%, respectively) is responsible for precipitation of additional phase particles: Q-Al₅Cu₂Mg₈Si₆ and θ -Al₂Cu. It has been established that homogenization results in total dissolution of the θ -Al₂Cu and Q-Al₅Cu₂Mg₈Si₆ primary phases and partial dissolution of β -Mg₂Si. Needle-like and Chinese-script α -Al₈Fe₂Si and β -Al₅FeSi were transformed into spheroidal α -Al(FeMn)Si particles. The maximal consolidation of the 6xxx alloys is a result of precipitation of metastable particles, the transient β'' , β' , and Q'/ θ' phases (6061 alloy) with high dispersion. The highest mechanical properties were achieved after holding in the temperature of 565°C/6h, supersaturated in water, and aging at 175°C/10–20h (T6). The decohesion process in the presence of tensile stresses in the room temperature proceeds through nucleation, the growth and joining of the voids, as well as the cracking of the primary and secondary large-sized intermetallic phase particles. The increase of deformation temperature up to 300°C causes the changes of the nucleation source and joining of voids—it occurs mainly along the matrix–particle interface.

Keywords: 6xxx Aluminum alloys; Fracture toughness; Heat treatment; Intermetallic phases; Mechanical properties; Microstructure; Solidification.

INTRODUCTION

6xxx-series aluminum alloys (AlMgSi) occupy a special place among light metals applied in modern technology. The development of main branches of industry is inseparably related to manufacture and processing of aluminum alloys, which are characterized by higher mechanical properties, especially relative tensile strength (R_m/δ), low density, high corrosion resistance, weldability, and plastic workability, compared to those currently used. Those alloys are an important group of materials applied mainly for moderately loaded elements of aircrafts, helicopters, and automotive vehicle rolling stock, as well as in the building industry.

AlMgSi alloys have multiple phases, therefore their mechanical properties are determined by microstructure—mainly morphology of phase components, including metastable and stable precipitates of strengthening phases, which precipitate during both primary solidification and heat treatment (T6). Besides the grains of α -Al matrix, precipitates of complex intermetallic phases, e.g., two-component phase β -Mg₂Si, three-component phases Al₈Fe₂Si and Al₅FeSi with the shape of lamellae and polyhedra, and also

four-component phase Al(FeMn)Si with Chinese script-like morphology, are phase constituents of AlMgSi alloys. Among 6xxx-series alloys that contain Cu addition, phase precipitates θ -Al₂Cu, Q-Al₅Cu₂Mg₈Si₆, and π -Al₈Si₆Mg₃Fe are present.

The intermetallic phases are primary alloy components and form during the solidification process, most commonly as a result of peritectic reaction involving intermetallic phases Al₅FeSi, Al₆(FeMn), AlMnSi, and Al₃Fe. They can also arise due to nucleation on interphase boundaries (e.g., Al₆(FeMn)/ α -Al) and precipitate in a form of highly dispersed precipitates, from solid solution α -Al, during slow cooling or heat treatment process. In many cases, the state of microstructure has to provide stability of properties in demanding operating conditions and technological processes (plastic working and welding). During the process of microstructure formation, which determines the mechanical properties of the end product, heat treatment, in addition to chemical composition, plays an important role. Therefore, research was conducted in order to establish a role of microstructure phase components, determined by chemical composition and conditions of heat treatment process (T6), during development of mechanical properties and

performance of following 6xxx-series aluminum alloys: 6005, 6063, 6061, 6066, and 6082. Phase components of microstructure were identified for alloys in as-cast state and after heat treatment. It was shown that the conditions of heat treatment (homogenization and precipitation strengthening – T6 – solutionizing + artificial aging) have an influence on the change of chemical composition and the morphology of microstructure phase constituents, also on chemical properties, including crack resistance which is a basic criterion for application in aviation industry. The author attempted to determine the role of precipitates of intermetallic phases during the fracture process of analyzed alloys. The fractographic analysis of cracks (SEM—scanning electron microscopy, light microscopy) was conducted in order to analyze the influence of microstructure components, on the formation of local mechanism and decohesion path, depending on the state of 6xxx-series alloys.

INFLUENCE OF CHEMICAL COMPOSITION ON THE MICROSTRUCTURE OF 6XXX-SERIES ALUMINUM ALLOYS

6xxx-series aluminum alloys are characterized by multi-phase structure. The precipitates of complex intermetallic phases are, in addition to solution (α) of silicon and magnesium in aluminum, basic components of phase microstructure of AlMgSi alloys.^[1–4] A part of those is formed due to interaction between aluminum and main alloy elements (Mg and Si) with transition metals, especially Cu, Mn, Cr, Ni, and Ti.^[1,5] The remaining ones are formed by elements which are difficult to remove in the course of metallurgical process of aluminum (e.g., Fe, Si).^[6–15] They are characterized by low solubility in solid solution which becomes lower with the decrease in temperature.^[1,2,11,15,16] A low amount of those elements leads to creation of distinct phase component in the form of intermetallic phase precipitates which arise in a course of alloys solidification process, most commonly, as a result of peritectic and eutectic transformations. Primary precipitates, formed during the solidification process, differ in morphology (“Chinese script,” lamellae, polyhedra, needles) and color (Fig. 1).

Among contaminants that are present in technical aluminum alloys, iron has the largest influence on change of their microstructure and mechanical properties.^[11–5,15,16] In microstructure of 6xxx-series aluminum alloys that contain iron, precipitates of two intermetallic phases are dominant: β -Al₅FeSi and α _H-Al₈Fe₂Si (Fig. 1). Precipitates of α _H-Al₈Fe₂Si phase with Chinese script morphology, also lamellar-structure, and needle-like β -Al₅FeSi phases are susceptible to cracking and reduce plastic workability of 6xxx-series alloys. During plastic deformation process of these alloys, precipitates are cracking (microcracks) and, consequently, prematurely damaged. Therefore, understanding the mechanism of formation of intermetallic phase precipitates, also control over their chemical composition, relative volume, and distribution in matrix, is of practical and economic meaning.

In order to identify the precipitates of intermetallic phases, which are present in the microstructure of investigated alloys 6005 (0.56% Mg, 0.75% Si, 0.12% Mn, 0.038% Cu, 0.20% Fe), 6063 (0.55% Mg, 0.55% Si, 0.07% Mn, 0.026% Cu, 0.18% Fe), 6061 (1.07% Mg, 0.78% Si, 0.15% Mn, 0.35% Cu, 0.16% Fe), 6066 (1.33% Mg, 1.51% Si, 0.83% Mn, 0.95% Cu, 0.18% Fe), and 6082 (0.76% Mg, 1.0% Si, 0.56% Mn, 0.022% Cu, 0.16% Fe), a microscopic observations using light, scanning, and transmission electron microscopes (including EDS—energy-dispersive X-ray spectroscopy), also X-ray measurement, were conducted. These results were used as a base for establishing the influence of alloying elements content on the phase composition of analyzed alloys. In the case of 6063 alloy with the lowest content of alloying elements, a presence of silicon atoms and intermetallic phases, namely, three-component α -Al₈Fe₂Si and β -Al₅FeSi with lamellar morphology, two-component β -Mg₂Si with Chinese script morphology, and four-component α -Al(FeMn)Si in the interdendritic spaces of solid solution α -Al, was observed (Figs. 1a and 2a, Table 1).

The performed analysis of microstructure of 6005 and 6082 alloys with higher content of Mg (0.56% and 0.76%), Si (0.77% and 1.0%), and addition of Mn revealed that material in the as-cast state is characterized by the presence of the following phases: two-component (β -Mg₂Si, Al₆Mn, and

Fig. 1 The microstructure of alloys (a) 6063 and (b) 6082 in the as-cast state visible precipitates of phases: β -Mg₂Si, β -Al₅FeSi, α -Al₁₂(FeMn)₃Si, and Si

Fig. 2 X-ray diffraction results for alloys: (a) 6005, (b) 6063, (c) 6061, and (d) 6082 in the as-cast state

Al_6Fe), three-component ($\beta\text{-Al}_5\text{FeSi}$ and $\alpha\text{-Al}_3\text{Fe}_2\text{Si}$), and four-component ($\alpha\text{-Al}_{12}(\text{FeMn})_3\text{Si}$). In the case of 6082 alloy, a five-component phase ($\alpha\text{-Al}_{12}(\text{FeMn})\text{Mg}_3\text{Si}_6$) was detected as well (Figs. 2 and 3, Table 1).

Increasing copper content in 6xxx-series alloys (0.35%—alloy 6061 and 0.95%—alloy 6066) leads to precipitation—in addition to crystals of free silicon and precipitates of phases $\beta\text{-Mg}_2\text{Si}$, $\beta\text{-Al}_5\text{FeSi}$, and $\alpha\text{-Al}_{12}(\text{FeMn})_3\text{Si}$ —phase precipitates which are rich in copper, mainly in the form of $\text{Q-Al}_3\text{Cu}_2\text{Mg}_8\text{Si}_6$ and $\theta\text{-Al}_2\text{Cu}$ (Fig. 3c and 3d). The detailed characterization of intermetallic phases that are present in the analyzed 6xxx-series aluminum alloys is presented in Table 1.

INFLUENCE OF HEAT TREATMENT ON THE MICROSTRUCTURE AND PROPERTIES OF 6XXX-SERIES ALUMINUM ALLOYS

Homogenizing

The homogenizing process of 6xxx-series aluminum alloys is used to prepare ingots for plastic working. Literature data indicate that ~80% of annual manufacture of

extruded aluminum products is made of 6xxx-series aluminum alloys.^[22,23] The homogenizing process of ingots is usually performed, depending on the chemical composition of 6xxx-series alloy, in the temperature range from 530°C to 600°C for 6–14 h (Fig. 4).

It has been established that during high-temperature heat treatment (homogenizing), the following material properties develop:

- Homogeneous distribution of alloy components in the $\alpha\text{-Al}$ matrix.
- Dissolution of low-alloyed eutectic mixture $\text{Si} + \text{Mg}_2\text{Si}$.
- Obtaining proper precipitates morphology for intermetallic phases formed by aluminum and transition metals (Fe, Mn, Cr, and Zr).

During homogenizing of 6xxx-series alloys in temperature range from 530°C to 600°C, atoms of Mg and Si can entirely enter the solid solution $\alpha\text{-Al}$, already after initial 2 h.^[2,22] The presence of Mn and Sr additions results in reduction of process duration and the decrease of homogenization temperature.^[2,3] Manganese, chromium, and zirconium are introduced mainly in order to form, during homogenization and solution heat treatment, stable,

noncoherent, and highly dispersed precipitates of strengthening phases. Their presence influences also the solutionizing effect and kinetics of low-temperature heat treatment and induces the initiation of heterogeneous nucleation. Additionally, after homogenizing, the remaining Mn and Cr atoms in solid solution α -Al allow the obtaining of an additional effect of precipitation hardening.^[25] Concentration of these elements cannot exceed the established critical value. Their higher content results in lowering of plastic workability.^[24] Lamellar and needle-like precipitates of β - Al_5FeSi phase have particularly unfavorable influence on plastic workability. Precipitates of this phase, which are present in the microstructure of 6xxx-series alloys, induce a local concentration of stress and lower its plastic properties. The presence of manganese atoms has decisive influence on improvement of deformability of 6xxx-series alloys. During homogenization treatment, a transition of lamellar precipitates of β - Al_5FeSi phase into spheroidal phase α - AlFeMnSi precipitates occurs in the presence of manganese atoms (Fig. 5).^[11,19]

During the homogenizing treatment of 6xxx-series alloys that contain Cu, in solid solution α -Al, a partial or

total dissolution of primary precipitates of eutectic phases with copper occurs: θ - Al_2Cu and $\text{Q-Al}_5\text{Cu}_2\text{Mg}_8\text{Si}_6$ (Fig. 5). Additionally, primary phase precipitates β - Mg_2Si dissolve partially in solid solution α -Al. Dissolution of β phase is particularly intensive during few initial hours of homogenizing, at the temperature of 565°C (3–10 h). Increasing the process duration does not result in growth of solubility of β - Mg_2Si phase (saturated solution, Fig. 6); however, it leads to change of shape of β - Mg_2Si precipitates, which are not dissolved in solid solution α -Al, from Chinese script in the as-cast state, through rounding off of their edges to spheroidal shape (after 48-h process).

Influence of Chemical Composition and Conditions of Thermal Treatment T6 on the Microstructure and Mechanical Properties of 6XXX-Series Alloy

Strengthening of precipitated particles of second phase is known for years and commonly applied method of increasing mechanical properties of aluminum alloys, including 6xxx-series alloys. During annealing of those

Fig. 5 The microstructure of 6066 alloy (a) in the as-cast state and (b) after homogenizing at the temperature of 565°C for 48 h

alloys at temperature above the solvus line, the particles of phases— β -Mg₂Si, θ -Al₂Cu, and Q-Al₃Cu₂Mg₈Si₆—dissolve in solid solution α -Al. Rapid cooling of alloys down to room temperature (solutionizing) leads to formation of solid solution α -Al in the “frozen” state (thermodynamic disequilibrium). In such solution, a thermodynamic force is created which accelerates the decomposition process and reaching the equilibrium state. The sequence of strengthening phase precipitation from solutionized 6xxx-series alloys proceeds according to general, most frequently described in literature, scheme:^[19,24,25]

where α -Al is the solutionized solid solution; GP is the Guinier-Preston zones, β'' and β' are the metastable, transient phases; and $\beta(\text{Mg}_2\text{Si})$ is the stable, equilibrium phase (Fig. 7).

During the aging process, at its initial stage, particles of metastable, transient phases precipitate from solutionized solid solution α -Al. Type of those phases and sequence of their precipitation from solutionized solutions depend on chemical composition of alloys and conditions of heat treatment. Highly dispersed particles of metastable, transient phases, as well as their similar morphology, make determination of their crystal structure impossible. Application of highly advanced techniques of microscopic observations (high-resolution electron microscopy) allowed to perform exact identification and characterization of metastable, transient phases in 6xxx-series alloys. The analysis of the results of conducted research^[25–27] shows that the decomposition process of solid solution α -Al is significantly more complex than the currently applied (Eq. 1). Detailed characterization of phases that strengthen AlMgSi alloys is presented in Table 2. At the initial stage of decomposition of

Fig. 7 Differential scanning calorimetry (DSC) thermogram of solutionized 6005 alloy, heated up to the temperature of 500°C with a rate of 10°C/min

solutionized solid solution α -Al, atoms of Mg and Si form clusters that are coherent with matrix (GPI and GPII zones). They have spherical shape and diameter ranging from 1 to 3 nm. The content ratio for Mg/Si is usually below 1.^[1,25] GPII zones are partially coherent with matrix. They are similar to metastable β'' phase and attain shape of needles, parallel to $\langle 100 \rangle$ plane of matrix. GPII zones solidify in monoclinic, base-centered structure ($a = 0.153 \pm 0.01$ nm, $b = 0.405$ nm, $c = 0.684 \pm 0.02$ nm).^[27] During the following stage of decomposition process for solutionized solid solution α -Al, partially coherent, highly dispersed particles of metastable intermediate phases precipitate: needle-like β'' phase and, afterward, β' phase in a form of lamellae or rods, parallel to direction $\langle 100 \rangle$ of the matrix (Table 2). The precipitates of metastable β'' phase maintain coherence with the matrix, along the direction parallel to needles, also partial coherence, toward the perpendicular direction. Matsuda^[28] observed additional metastable phases (type A, B, and C) in alloys with higher Si content (Table 2). Precipitates of those phases are present in alloys that do not contain Cu and have higher content of Si, in comparison with the corresponding equilibrium phase Mg₂Si (Table 1). The probability of precipitation for particles of metastable type A, B, and C phases grows with the increase of Si content in AlMgSi alloys.^[29] During the aging process, precipitates of type B phase arise in the first instance, in addition to metastable β' phase. Increasing the amount of Si content up to 0.4% leads to dissolution of β' phase particles; type B phase is dominant. Further aging favors the formation of particles of metastable type A and C phases. Simultaneously, β' and type B phases decay (Table 2, Fig. 8). At the final stage of the aging process, a stable, equilibrium (noncoherent with matrix) $\beta(\text{Mg}_2\text{Si})$ phase is formed. It crystallizes in regular structure BCC—body-centered cubic lattice), in the form of lamellae.

Table 2 Characterization of metastable, transitional phases and stable, equilibrium phase β for 6xxx-series alloys

Phase	Equation	Morphology/typical size	Structure	Content ratio Mg/Si	References

Increased content of copper in 6xxx-series alloys influences also the precipitation process of strengthening phase particles from solutionized AlMgSi(Cu) alloys.^[30] It was concluded that even low amount of copper (0.5%) in AlMgSi alloys results in change of precipitation sequence of strengthening phases in solutionized solutions.^[20,25,30] Apart from the main strengthening particles of β -Mg₂Si phase, during aging of alloys with addition of Cu, precipitates of metastable, transient phases appear. These

phases—Q' and θ' —contain Cu and precede precipitation of stable particles of equilibrium phases Q-(AlMgSiCu) and θ -Al₂Cu.^[20,30] The precipitation process in alloys that contain copper proceeds according to the following sequences:

Fig. 8 The influence of Si content on the type and relative volume of metastable phases precipitated in Al-1.0%Mg₂Si-X%Si alloy, during aging process performed in the temperature of 250°C^[29]

The analysis of literature data^[26–30] concerning the precipitation process from solutionized solutions was a basis for developing scheme of precipitation for metastable phases. Depending on the chemical composition of 6xxx-series aluminum alloys, three subgroups were distinguished (Table 3). For a subgroup of AlMgSi alloys, the atomic amount ratio Mg/Si equals to 2:1 and corresponds to Mg₂Si phase.^[1,25,26] The second subgroup consists of AlMgSi+Si alloys with higher Si content, compared to corresponding Mg₂Si phase^[25,29] (Table 3). The third one includes AlMgSi+Cu alloys with the addition of Cu^[30] (Table 3).

The investigation of mechanical properties of analyzed alloys confirmed that particles of transient, metastable phases that precipitate during the aging process cause the increase in mechanical properties of 6xxx-series aluminum alloys. Hardness measurements were conducted in specific time intervals in order to proof the influence of temperature (150°C, 175°C, and 205°C) and the duration of aging on the properties of 6005, 6061, 6063, and 6082 alloys. The obtained results indicate that hardness of those alloys depends on conditions of precipitation strengthening process (Fig. 9). Highest value (115 HB—6005 alloy, 128 HB—6061 alloy, 105 HB—6063 alloy, and 133 HB—6082 alloy) was reached after ~70-h aging at the temperature of 150°C. It should be mentioned that 6005 and 6061 alloys are characterized by slightly lower hardness values (107 HB—6005 alloy and 126 HB—6061 alloy) obtained after

aging at the temperature of 205°C which is shorter by ~6–8 h. Hardness of 6063 and 6082 alloys, after aging in the temperature of 150°C, is higher by ~20 HB than hardness of those materials aged at the temperatures of 175°C and 205°C. However, the time of reaching the maximum value of hardness is longer even by several dozens of hours (Figs. 9, 10a).

Independently of aging temperature, 6063 alloy with the lowest content of Si, Mg, and Mn is characterized by lowest hardness. After aging in the temperature of 150°C, 6061 and 6082 alloys have similar values of maximum hardness (128.2 HB—6061 alloy and 132.8 HB—6082 alloy). 6061 alloy in T6 state is characterized by the highest hardness among analyzed alloys, which were submitted to aging in the temperature of 150°C or 175°C (Figs. 9, 10b). The analysis of obtained results showed that the increase of aging temperature reduces the time needed for reaching maximum hardness of investigated alloys (Fig. 10a). Highest hardness values were attained after the aging process was performed at the temperature of 150°C. It was determined that, after heat treatment T6, 6061 and 6082 alloys reached maximum hardness, independently of assumed value of aging temperature. These were also characterized by the largest content of alloy elements—Mg and Si, and also Mn, Cu, and Fe (Fig. 10b).

The results of calorimetric analysis and investigation of mechanical properties confirm that maximum strengthening (increase of hardness and tensile strength) of 6xxx-series aluminum alloys is caused by precipitation process, which proceeds during aging of solutionized solid solution α -Al of GPII zone and particles of metastable β'' phase. Appearance of β' phase in microstructure (overaged state) leads to reduction of mechanical properties of those alloys (Fig. 11). Increasing the duration of aging process for 6005 and 6082 alloys, at the temperatures of 175°C and 220°C, leads to expansion of lamellar precipitates of strengthening β -Mg₂Si phase, from the length of ~0.05 μ m (maximum hardness, Fig. 12a,b) to ~200 nm, after 6 h of aging and to ~600 nm (overaged state, Fig. 12c,d). As a consequence, expansion of β -Mg₂Si phase leads to decrease in the mechanical properties of those alloys (Figs. 9–11).

The results analysis performed for static tensile test (Fig. 13) was a base for establishing the influence of heat treatment (T6) conditions on the mechanical (R_m , $R_{0.2}$) and plastic (A_5) properties of 6005, 6061, 6063, and 6082 alloys. As in the case of hardness, aging of 6005, 6061, 6063, and 6082 alloys at the temperature of 150°C leads to the increase of $R_{0.2}$ and R_m values, as well as the duration of aging process. After ~60 h of aging, alloys reach maximum R_m value (6005 and 6063 alloys—300 MPa, 6061 alloy—350 MPa and 6082 alloy—330 MPa). Rising the temperature up to 175°C reduces aging time down to 5–10 h, until similar tensile strength (R_m) is obtained. After that time of the aging process, the strengthening effect (growth of R_m) is small or R_m value diminishes (after 50 h). Only 6061 alloy

is characterized by constant mechanical properties, independently of the temperature and duration of the aging process (Fig. 13).

Analysis of obtained results allows the statement that 175°C is an effective aging temperature for 6xxx-series aluminum alloys. Aging in such temperature allows to maximize tensile and yield strength while maintaining good plasticity (Fig. 13). Analyzed alloys, except 6082 alloy, show the lowest mechanical properties after aging

performed at the highest temperature value (205°C, Fig. 13). The conducted research includes analysis of the influence of heat treatment conditions (T6) and fracture plane orientation (relative to direction of plastic deformation) on crack resistance and tensile strength in the presence of sharp notch R_m^k . It was established that 6061 and 6082 alloys, aged in the temperature of 175°C, with high content of alloy elements (mainly Mg and Si), are characterized by the highest tensile strength in the presence of sharp notch R_m^k . It concerns samples that are oriented perpendicularly to the direction of plastic working L-T—longitudinal transverse (Table 4).

The crack resistance K_{Ic} and critical stress intensity factor K_{Ic} for alloys, which belong to this group, depends on the content of alloying elements, conditions of performed heat treatment (T6), morphology of its microstructure, and orientation of fracture plane, relative to the direction of plastic deformation. (Table 4).

The literature data concerning cracking of materials strengthened with precipitates of the second phase^[31–42] and the fractographic analysis state that alloys with lower relative volume of intermetallic phase particles are characterized by larger crack resistance. For example, 6063 and 6005 alloys with lower relative volume of intermetallic phase precipitates ($V_v = 1.9\%$ —6063 alloy and 2.2% —6005 alloy) are characterized by high crack resistance, in comparison with 6061 and 6082 alloys ($V_v = 5.8\%$ —6061 alloy and 5.4% —6082 alloy) (Table 4). In case of precipitation-strengthened 6005 and 6063 alloys with low relative volume of intermetallic phases V_v , intercrystalline cracking is a dominant phenomenon. Primary areas of void

nucleation are particles of precipitated secondary strengthening phases: $\beta\text{-Mg}_2\text{Si}$. The crack develops by nucleation, growth, and merging of voids—at the final stage of plastic deformation (Fig. 14a, 14b).

During cracking of alloys characterized by higher relative volume of intermetallic phases, e.g., 6061 and 6082, primary and secondary precipitates of hard and brittle intermetallic phase particles (Al_6Fe , $\beta\text{-Al}_5\text{FeSi}$ and $\alpha\text{-Al}_8\text{Fe}_2\text{Si}$, and $\alpha\text{-Al}_{12}(\text{FeMn})_3\text{Si}$ and $\text{Q-Al}_3\text{Cu}_2\text{Mg}_8\text{Si}_6$) play an important role, in addition to strengthening particles of secondary phases. Decohesion processes in those alloys are often initiated by cracking of large intermetallic phase particles in a form of needles, rods, or Chinese script (Fig. 14c–f). Decohesion process of 6xxx-series alloys is influenced also by the orientation of primary intermetallic phase particles, relative to the loading

direction (plastic deformation). Observations conducted on polished surfaces of samples and their fractures after static tensile test confirmed the presence of decohesion and fragmentation of the majority of particles of primary intermetallic phases, mainly $\beta\text{-Al}_5\text{FeSi}$, $\alpha\text{-Al}_8\text{Fe}_2\text{Si}$, and $\alpha\text{-Al}_{12}(\text{FeMn})_3\text{Si}$, oriented under angle $0^\circ\text{--}45^\circ$ to loading direction (Fig. 14c–f). In the presence of precipitates that form an angle $45^\circ\text{--}90^\circ$ with the loading direction, decohesion of alloy proceeds mainly along *matrix/particle* interphase surface (Fig. 14g,h). The fractographic analysis of fracture profiles and their surfaces, conducted after static tensile test at room temperature, allowed to develop a schematic description of the influence of orientation of large non-coherent intermetallic phase particles (relative to tensile force), on the cracking mechanism of strengthened 6xxx-series aluminum alloys. It has been established

Fig. 14 The images of ductile fracture of alloys: (a) 6005 and (b) 6063 after precipitation strengthening

Fig. 15 Scheme of crack initiation and propagation in strengthened 6xxx-series aluminum alloys, depending on the orientation of intermetallic phase particles, relative to the direction of load and temperature influence

that deformation temperature strongly influences the crack resistance of 6xxx-series aluminum alloys. The fractographic research of samples fractures, after tensile test performed at the temperature of 300°C, showed that cracking in elevated temperature proceeds only as the result of nucleation and merging of voids along the *matrix/particle* interface boundary. High degree of plastic deformation of matrix, in the vicinity of interface boundary, leads to growth of critical stress σ_{kryt} . As a result, a nucleation process proceeds and voids start to grow. The images of fracture surfaces are characterized mainly by the presence of voids and pits with different sizes. They depict the size and shape of precipitates of intermetallic phase. Practically, no presence of fractured intermetallic phase particles was observed (Fig. 15).

CONCLUSIONS

Based on performed research and analyses of obtained results, the following conclusions were drawn:

1. The morphology of phase components of 6005, 6061, 6063, and 6082 alloys depends chiefly on the content of main elements Mg and Si, also addition of transient metals Mn, Cu, and Fe. The microstructure of 6063 alloy contains primary precipitates of two-component phase $\beta\text{-Mg}_2\text{Si}$, three-component phases $\alpha(\text{Al}_8\text{Fe}_2\text{Si})$ and $\beta(\text{Al}_3\text{FeSi})$ in the form of needles and lamellae with sharp edges, and also four-component phase $\alpha\text{-Al}(\text{FeMn})\text{Si}$. In case of 6005 and 6082 alloys, higher content of elements,

including manganese (0.5%), leads to formation of two-component phases Al_6Fe and Al_6Mn , and five-component phase $\alpha\text{-Al}_{12}(\text{FeMn})\text{Mg}_3\text{Si}_6$, in addition to $\beta\text{-Mg}_2\text{Si}$, $\alpha(\text{Al}_8\text{Fe}_2\text{Si})$, $\beta(\text{Al}_5\text{FeSi})$, and $\alpha\text{-Al}(\text{FeMn})\text{Si}$ phases. However, higher content of copper in 6061 and 6066 alloys (correspondingly 0.35% and 0.95%) results, additionally, in precipitation of phases $\text{Q-Al}_5\text{Cu}_2\text{Mg}_8\text{Si}_6$ and $\theta\text{-Al}_2\text{Cu}$.

2. The homogenization process, performed at the temperature of 565°C , alters the morphology of intermetallic phase precipitates. After $\sim 5\text{--}10\text{ h}$ of treatment, lamellar and needle-like particles of $\beta\text{-Al}_5\text{FeSi}$ phase coagulate and transform into precipitates of $\alpha\text{-AlFeSiMn}$ phase. Simultaneously, a partial dissolution of primary, eutectic precipitates of $\beta\text{-Mg}_2\text{Si}$ phase and a complete dissolution of eutectic precipitates of phases with copper— $\theta\text{-Al}_2\text{Cu}$ and $\text{Q-Al}_5\text{Cu}_2\text{Mg}_8\text{Si}_6$ —and silicon proceeds. The morphology of remaining, undissolved precipitates of $\beta\text{-Mg}_2\text{Si}$ phase changes into Chinese script through rounding off of edges, until spheroidal precipitates are formed.
3. In alloys 6005, 6063, and 6082, the precipitation process of strengthening phases proceeds according to the scheme: zones $\text{GP} \rightarrow \beta'' \rightarrow \beta' \rightarrow \beta(\text{Mg}_2\text{Si})$, whereas in 6061 alloys: zones $\text{GP} \rightarrow \beta'' \rightarrow \beta' + \text{Q}/\theta' \rightarrow \beta(\text{Mg}_2\text{Si}) + \text{Q}/\theta$. Maximum strengthening is reached as a result of precipitation of metastable, transient phases β'' and β' , in a form of mutually perpendicular lamellae, formed on planes $\{100\}$ of solid solution $\alpha\text{-Al}$ and precipitates of Q/θ' phases (6061 alloy).
4. Changes of morphology of phase components in the microstructure of 6xxx-series alloys during aging process determine the improvement of their mechanical properties. Precipitates of transient, highly dispersed phases β'' and β' provide the maximum tensile strength while maintaining high plastic properties. Such state of microstructure also ensures satisfactory crack resistance.
5. The highest mechanical properties of analyzed alloys—6005 ($R_{0.2} = 272\text{ MPa}$, $R_m = 291\text{ MPa}$, $R_m^k = 466\text{ MPa}$, $K_{Ic} = 54.8\text{ MPa}\cdot\text{m}^{1/2}$), 6061 ($R_{0.2} = 331\text{ MPa}$, $R_m = 353\text{ MPa}$, $R_m^k = 565\text{ MPa}$, $K_{Ic} = 43.34\text{ MPa}\cdot\text{m}^{1/2}$), 6063 ($R_{0.2} = 271\text{ MPa}$, $R_m = 290\text{ MPa}$, $R_m^k = 378\text{ MPa}$), and 6082 ($R_{0.2} = 315\text{ MPa}$, $R_m = 338\text{ MPa}$, $R_m^k = 529\text{ MPa}$, $K_{Ic} = 43.34\text{ MPa}\cdot\text{m}^{1/2}$)—were obtained after heating up at the temperature of $565^\circ\text{C}/6\text{ h}$, solutionizing in water, and aging at the temperature of 175°C for $\sim 20\text{ h}$ (6005 and 6061 alloys) and $\sim 10\text{ h}$ (6063 and 6082 alloys). Increasing the duration of aging, performed at the temperature of 150°C and 175°C , leads to precipitation and growth (from 20 nm —maximum hardness up to 600 nm) of stable precipitates of $\beta\text{-Mg}_2\text{Si}$ phase. Those alloys, if overaged, are characterized by lower crack resistance and slightly diminished tensile properties. 6005 alloys have the highest crack resistance ($K_{Ic} = 54.8\text{ MPa}\cdot\text{m}^{1/2}$).
6. Independently of the state (as-cast, submitted to plastic working or precipitation strengthened—T6), 6061 aluminum alloy with the highest content of Mg, Si, and Cu is characterized by the highest tensile strength ($R_m = 370\text{ MPa}$) and yield stress ($R_{0.2} = 300\text{ MPa}$) among all analyzed alloys. It also maintains good plastic properties ($A = 12\%\text{--}14\%$, $Z = 35\%\text{--}40\%$) and crack resistance.
7. The mechanism of cracking in 6xxx-series aluminum alloys is determined by the state of microstructure and plastic deformation temperature. Decohesion for tensile stress at room temperature is a result of nucleation, growth, and merging of voids. Often, it is also caused by cracking of large primary and secondary precipitates of intermetallic phases. In the elevated temperature of $\sim 300^\circ\text{C}$, decohesion occurs mainly due to nucleation and merging of voids, along the *matrix/precipitate* interfacial boundary. 6063 and 6005 alloys with lower relative volume of precipitates ($V_v = 1.9\%$ and 2.2%) are characterized by higher crack resistance, compared to 6061, 6066, and 6082 with higher relative volume of intermetallic phases precipitates ($V_v = 5.4\%$)—large amount of micro-areas (*matrix/precipitate*) susceptible to nucleation and void growth.

Additive Manufacturing of Aluminum Alloys

Sriram Praneeth Isanaka, Sreekar Karnati, and Frank Liou

Department of Mechanical and Aerospace Engineering, Missouri University of Science and Technology, 400 W 13th St, 217 Toomey Hall, Rolla, MO, 65401, United States

Abstract

Successful additive manufacturing (AM) of aluminum alloys has been demonstrated using a number of processes, which is the focus of this article. Utilization of some aluminum alloys with relatively low reflectivity coupled with process optimization to achieve high retained energy densities enabled the successful deposition of aluminum–silicon alloys that were previously manufactured exclusively using casting processes. The design flexibility of AM processes coupled to the ability to direct energy and material to specific spatial locations has also been used to demonstrate the ability to join dissimilar aluminum alloys, with applicability toward functional grading and repair. Researchers have shown that the additively manufactured alloys exhibit comparable and, in cases, improved mechanical properties to their conventional counterparts with highly refined grain structures. Elaborate investigations into their microstructures to determine the causality of the mechanical properties are also discussed in detail. Understanding the relationship between these desired high retained energy densities and the factors favoring them, including the alloy composition, input energy, and the deposition speed and volume, plays a pivotal role toward successful additive manufacture. With further process parameter optimization and the development of raw material supply chains that can create and tailor alloys based on need, the applicability of these AM processes can be adapted to many more aluminum alloys and can be tailored to serve a wide range of industries.

INTRODUCTION

While additive manufacturing (AM) processes have provided an economical alternative for the manufacture of exotic materials, their embrace of aluminum alloys has not been widespread. Aluminum alloys possess high thermal conductivities and exhibit high reflectivity to incident light, which complicates their processing and has even made some of them difficult to weld. This article investigates the issues that aluminum alloys exhibit when manufactured by AM processes such as selective laser sintering (SLS) (powder bed), ultrasonic consolidation (UC), gas metal arc welding (GMAW) three-dimensional (3D) printing, and blown powder deposition (powder fed). The causes behind successfully processing aluminum alloys have been identified by many researchers by understanding the importance of input and retained energy densities and relating both to the factors affecting them. This article elaborates on researchers' investigations into these factors including the direct (laser power, deposition volume, deposition speed, etc.) and indirect (alloy composition, powder manufacturing process, system thermal mass, etc.) process parameters

associated with each. By identifying and mapping the ideal combination and parameters of these factors, researchers have demonstrated the ability to additively manufacture, functional grade, and repair using aluminum alloys. This article focuses on the use of alloys with high aluminum content (Al >50%), coupled to processes capable of the direct processing of raw material stock into end useable products. It does not include the details of aluminum alloy casting, powder metal sintering, and infiltration techniques that are sometimes classified as additive processes.

What is AM?

In subtractive manufacturing, which has been the dominant manufacturing strategy of the past century, material is systematically removed from large volumes of raw material to achieve the desired 3D shape. AM reverses this conventional rationale by utilizing and depositing only the requisite material in the desired locations to produce 3D geometries. By utilizing computer aided design models to directly deposit the materials, AM processes afford significant savings in the time, cost, and man power needed

to manufacture components. AM processes have outgrown their humble beginnings in prototype manufacturing to become a viable alternate manufacturing strategy. AM processes have demonstrable capability in manufacturing components with infinite design flexibility and also using a wide range of materials that include metals, polymers, ceramics, and biological/biomimetics. This article elaborates on AM's expansion into the realm of aluminum and its alloys.

The Importance of Aluminum Alloys

Aluminum alloys have always been eagerly sought in the fixed wing aircraft industry due to their high strength-to-weight ratios, while their resistance to certain types of corrosion has enabled their use in shipping and rotary wing aircraft. Their low densities coupled to their ability to be heat treatable made them ideal candidates to replace conventional alloys like steel for a number of applications. Even the automotive industry is currently investigating their use to improve fuel efficiency. While possessing exceptional strength and stiffness characteristics, it is the high reflectivity to light and the high thermal conductivities they exhibit that have made them difficult to weld. As most AM processes have a high-energy source just as in welding, these properties also make them unsuitable for additive manufacture, until now. Coupling the advantages offered by AM to the favorable mechanical properties of aluminum alloys will create viable mass-market manufacturing strategies that will increase the adoption and implementation of both across the world.

AM PROCESSES CAPABLE OF MANUFACTURING ALUMINUM ALLOYS

Aluminum alloys by their metallic nature possess relatively high melting points and require significantly high-energy sources to achieve temperatures that will allow them to be shaped into usable forms. AM^[1,2] has both direct and indirect techniques that allow the user to reach the sintering and melting temperatures of aluminum alloys. This article focuses on powder-fed AM and powder bed AM that enable the direct processing of aluminum alloys by creating the energy density needed to reach the melting point of the alloys. Discussion will be provided on sheet lamination processes like UC that have also successfully demonstrated the ability to process aluminum alloys. The discussion will be extended into research efforts into the modification of conventional metal inert gas welding processes capable of 3D printing aluminum alloys components. Indirect techniques that require postprocess sintering or employ infiltration are not covered.

Powder-Fed Deposition

Powder-fed deposition, as the name implies, is an AM process that relies on the delivery of raw material, in powder form, with the aid of a stream of gas.^[3] These particles of the desired metals and alloys are transported to a melt pool created by a high-energy source (laser, electron beam, etc.) on a substrate.^[4] This gas stream also envelopes the melt pool region to ensure an inert environment that prevents oxidation and other detrimental effects from affecting the molten material. As observed in Fig. 1, the high-energy sources fuse these powder particles with the substrate to create a metallurgical bond. Typically, the table that supports the substrate has X-Y axes motion while the head that delivers the energy and material possesses Z-axis motion. These and possibly other motion mechanisms aid the deposition of material in a layer-by-layer manner to complete the manufacture of the desired 3D geometry. Powder-fed deposition apparatus are not restricted to three axes of motion, and many researchers and inventors have developed systems capable of five or more axes motion and even robotic actuation into seven axes. These implementations have further expanded on the already extensive design flexibility offered by powder-fed deposition systems.^[5] Powder-fed deposition systems have also shown significant flexibility toward the materials that they have processed and have successfully demonstrated the deposition of 3D geometries in steels,^[6] stainless steels, nickel alloys,^[7] cobalt alloys, titanium alloys, metal matrix composites, and even some ceramics.

The volume of research and development into powder-fed deposition systems has significantly improved their capability and applicability.^[8] Their unique ability to deliver both the material and energy to any spatial location has made them popular not just as AM processes, but also enabled materials research into functional grading^[9] and repair of legacy components.^[10,11] The high cooling rates inherent in powder-fed deposition have also helped

Fig. 1 A custom laser-aided powder-fed deposition apparatus at Missouri University of Science and Technology creating a 3D geometry using metal powder

in processing structurally amorphous materials and other high performance alloys and metal matrix composites that demand highly refined microstructures. The successful processing of aluminum alloy are powder-fed deposition's latest foray and come with a unique set of challenges and solutions that are detailed in the forthcoming sections.

Powder Bed Deposition

Another process that uses powder as raw material is the selective laser melting process; although the particle sizes involved are typically smaller ($<50\mu\text{m}$). In selective laser melting, illustrated in Fig. 2, the powder is preplaced in layers using rollers/wipers that transfer them from their storage containers and onto the workplace called a powder bed. Hence, the selective laser melting and other processes that employ powder beds such as SLS are classified as powder bed deposition processes.^[12] Once the powder has been uniformly distributed across the bed, a high-energy source (like a laser) traces across desired sections, thereby melting and fusing the particles in the layer. These sections are fused based on the path plans derived from the STL files and mimic the cross-sectional shape of the desired 3D geometry. The powder bed then moves down by one layer thickness, which allows the rollers to distribute another layer of material on the recently fused sections. The laser-aided processing is performed again, which not only creates a new layer of fused powder particles but also creates a metallurgical bond with its preceding layer. This procedure is repeated over and over until the desired 3D geometry is produced. The final

Fig. 2 A Renishaw powder bed selective laser melting machine at Missouri University of Science and Technology in the process of making multiple 3D parts

product is removed from the bed and cleaned of the unfused powder to achieve a component capable of end use.

Similar to powder-fed systems, powder bed systems are governed by controlling energy densities and monitoring the variables^[13,14] contributing to high retained energy density. Unlike powder-fed systems, the small particle size coupled to the use of galvo-mirror scanning system directed lasers enable powder bed systems to operate at exceptionally high scan speeds. While this has made them attractive to many manufacturers, the processing speed and lack of powder compaction leads to the creation of significant amount of porosity.^[15,16] Researchers are actively solving this^[17] by developing material dependent process maps^[18] and employing post process techniques like hot isostatic pressing to minimize or eliminate these pores. Powder bed systems are some of the oldest AM technologies in use, and their popularity has not only led to significant published research content, but has also enabled the development of off-the-shelf equipment that is currently being employed by the aerospace industry. By adopting these technologies, aerospace manufacturers have significantly improved the design flexibility and performance, while minimizing manufacturing complexity, time, cost, and the man power employed. With the evidence presented, powder bed selective laser melting systems have demonstrated significant material flexibility^[19,20] and have achieved greater success than blown powder deposition (BPD) systems in processing aluminum alloys.^[21]

Other AM Processes Manufacturing Aluminum Parts

UC is the process of directing high frequency sound energy waves to create material fusion. A commercially available apparatus and its principle components are shown in Fig. 3.^[22] The principle behind UC involves the transmission of sound energy through “horns” into thin foils that cause them to vibrate. This high-frequency vibration cleans up oxides on the surface, thereby fusing the virgin material surfaces.

UC is broadly classified as a sheet lamination process that welds sheets of raw material together to create a solid metallurgical bond.^[23] Any excess material is then machined off to achieve the desired 3D shape. In this regard, UC can be considered as a hybrid process that tries to unite the advantages of both additive and subtractive manufacturing into one cohesive solution. While a popular process for aluminum alloys,^[24,25] it has been demonstrated to work with stainless steels^[26] and metal matrix composites.^[27] It can even join dissimilar materials together, thereby offering the ability to functionally grade materials.^[28] The most important outcome of this process, namely, the bond strength between layers, is directly attributed to factors such as weld speed, normal force, and oscillation amplitude,^[29,30] which when closely controlled makes this process exceedingly flexible. By working at temperatures well

Fig. 3 A UC equipment and its principal components^[22]

below the melting point of materials, UC offers a means to embed electronics and other sensors to promote real time structural and performance monitoring.^[31]

GMAW as a 3D printing process was derived from the conventional metal inert gas welding process. The welding process utilizes energy from an arc with filament material to join two separate pieces into one component. While the consumables, the inert environment, and the energy sources were retained from the original process, the latest iterations have enhanced motion capabilities across multiple axes. This has changed a humble joining process into one capable of AM a multitude of materials. An example of multi-axis GMAW process is shown in Fig. 4.

Unlike other AM processes though, the energy densities and cooling rates achieved by GMAW are different. This, coupled to GMAW's ability to deposit large volumes of materials in short periods of time, lead to the creation of microstructures with much larger grain sizes. GMAW also does not offer the grain refinement capability of the other AM processes. One of its major advantages, though, is that it has been successfully employed to join a comprehensive list of materials over a period of decades. This data and the supply chain to create a near infinite volume and types of feedstock have been employed by researchers to convert GMAW-based 3D printing into a viable manufacturing strategy.

Fig. 4 A custom multi-axis GMAW apparatus including a hybrid machining process^[32]

ADVANTAGES OF ADDITIVELY MANUFACTURING ALUMINUM ALLOYS OVER CONVENTIONAL CASTING AND MACHINING TECHNIQUES

Conventionally, most aluminum alloy components have been subtractively machined, cast, or forged to their desired shapes and dimensions. While these techniques have efficiently served large supply chain demands across a multitude of sizes and have achieved excellent tolerance requirements, the achievements were at the expense of design flexibility. Component designs have always been adjusted to compensate for manufacturability, ease of assembly, and the availability of man power. Today's AM techniques offer an alternative strategy that is not restricted by these attributes of the past. AM techniques such as powder-fed deposition and powder bed deposition also offer significant advantages including

- *Infinite design customization:* AM has always offered economics when confronted by small batch sizes and large design complexity. The greater the design complexity, the greater the economics that can be realized by employing AM techniques over conventional manufacturing. Currently, aerospace companies such as Aerojet and Boeing have created component assemblies with dramatically reduced part counts while still achieving the desired design complexity and product performance.
- *Repairability:* A significant number of legacy aluminum components created with significant expense are scrapped when they reach their end of life or when subjected to damage. AM offers the ability to repair and remanufacture them to their former precision and performance characteristics. This not only provides environmental benefits but also significantly minimizes the cost, energy, and raw material expenditure toward replacements.
- *Feature addition to existing cast or forged parts:* While casting and subtractive manufacturing might not offer design flexibility, they do offer significant economies of scale and batch production. AM processes that can direct energy and material spatially offer an avenue to add complex features to existing forged and cast aluminum parts. This merges the benefits of batch production with the flexibility of AM, thereby offering economical yet unique product solutions.
- *Refine grains and modify microstructures:* The microstructures created by the casting and even some forging processes typically exhibit coarse grains. AM, on the other hand, with its high cooling rates, exhibits comparatively refined grain structures. These smaller grains exhibit favorable mechanical properties and dislocation mechanics compared the microstructures in their cast counterparts. The highly localized energy input and the thermal cycling inherent to layer deposition also offer an avenue to spatially remelt and

recrystallize specific zones and therefore locally alter microstructures.

- *Functional grading:* Conventional manufacturing techniques work with one material at a time. While there are methods to join dissimilar materials, few offer the material flexibility, the bond strength, and the localization offered by AM processes. AM offers the ability to join dissimilar aluminum alloys, and spatially improve characteristics based on functional need. For example, AM processes can be used to improve the corrosion and wear resistance of the surface of components or increase the load bearing capabilities across a desired axis. AM techniques with their material flexibility offer unrivaled ability to coat, functionally grade, and offer design solutions unavailable in the past.
- *Embedding components/electronics:* When moving into connected networks, some AM processes such as UC can provide the ability to embed electronics in components. Owing to the fact that UC does not reach exceedingly high temperatures when processing aluminum alloys, it offers the ability to embed both active and passive electronic devices in functional components. This can enable real-time structural health monitoring of critical components leading to preemptive prediction of failure. The difficulty in embedding electronics in components manufactured using subtractive processes is extensive and dramatically increases fastening mechanism numbers and complexity. Unless the sensors are shielded against high temperatures (above and beyond the melting point of materials), this concept is not even feasible using casting and other processes involving phase change.

THE PROCESSES, PROBLEMS, AND SOLUTIONS

The quality (geometric, metallurgical, and stochastic attributes) of parts produced by AM is governed by direct variables such as the input energy, the input material volume, shield gas employed, and the deposition speed, and other indirect ones such as the thermal conductivity, thermal mass, phase change mechanics, and reflectivity/absorptivity involved. All of these variables contribute to the retained energy density per unit volume per unit time, which is the primary determinant toward the creation and sustenance of a melt pool. It is important to note that while a stable melt pool is critical to the creation of high quality parts using AM, the melt pool's shape and size are dependent on the retained energy density. Owing to the fact that this retained energy density is difficult to measure and quantify, researchers typically use the input energy density as the guide to control the melt pool and therefore the quality of the parts that they produce. The logistics involved in creating and tailoring the raw material feedstock in the desired alloy compositions and ensuring their consistent feed to the AM processes is also important.

Powder-Fed Processes

The rationale behind retained energy density is of particular importance in the powder-fed deposition process when lasers of 1 kW power or less are employed with materials having high thermal conductivities. If the retained energy densities are insufficient and/or imparted to the substrate for an insufficient amount of time, the fusion between the powder particles and the substrate is poor. This has been confirmed by both literature and the authors' own research and is amplified in alloys that have both high reflectivity and thermal conductivity, like aluminum and copper.

An example of the poor bond achieved between the deposit and the substrate from the authors' investigation into joining dissimilar aluminum alloys is shown in Fig. 3.^[32] Some common solutions to increasing the retained energy density in powder-fed processes include employing higher power lasers, increasing absorptivity by using lasers in the other spectrums, slowing down the deposition speed, employing substrate heating or thermal insulation, and finally altering the spot size and therefore the intensity of the laser light. Pure Aluminum exhibits significant reflectivity to incident light^[33] and reflects 92% of visible light and 98% of medium and near infrared radiation as seen in Fig. 4. By employing differing alloying elements, the reflectivity of the aluminum alloys can be varied, and some of them can be made to be relatively more absorptive of the incident laser light. This increased absorptivity aids in the initiation of the melt pool and therefore the powder-fed deposition process. Typically, in powder-fed systems, the laser spot size is large, being around 2 mm in diameters or higher. Work performed by Dinda et al. indicated that this can be compensated for by employing aluminum alloys with relatively higher absorptivity (e.g., aluminum–silicon alloys) in conjunction with high-power lasers up to 2.25 kW.^[34]

The layer thickness achieved by Dinda et al. was also demonstrably higher than the typical values for steels, nickel alloys, titanium alloys, and so on. This phenomenon was also confirmed by Lei et al.,^[35] who laser welded customized powder feedstock that were mechanically alloyed to obtain 6063 Al–Si composites.^[36] Developing ideal process parameters without considering the substrate's and the feedstock's optical and thermal characteristics is insufficient to deposit and/or control the powder-fed deposition process. In other words, the limitation of using powder-fed deposition with aluminum alloys is the availability of relatively absorptive aluminum alloy feedstocks (Fig. 5).

The microstructural characteristics of powder-fed deposition manufactured aluminum–silicon alloys such as the 4047 Al shown in Fig. 6 was as anticipated. Powder-fed deposition while being an AM process deposits material one layer on top of the other. It was expected that this layer deposition coupled with repetitive thermal cycling that it promotes would lead to directional primary aluminum dendritic growth in a eutectic matrix. This was confirmed

Fig. 5 Poor bonding between the substrate and the deposit when depositing 4047 Al powder on a 2024 Al substrate^[32]

Fig. 6 A comparison of the absorptivity of metals when exposed to laser energy of multiple wavelengths^[33]

by the authors' own research shown in Fig. 7 and reinforced through data from literature.^[34] While the hypoeutectic nature of the deposition did not change, eutectic microstructure was noticed to be both fine and coarse based on its location in the deposit. This inhomogeneity is expected to extend into the mechanical properties leading to anisotropy in the performance. The recrystallization of the past layer during current deposition and the constant thermal cycling leads to the coarsening of both the primary aluminum dendrites and the eutectic matrix whose effects are noticed to be more pronounced at the layer boundaries shown in Fig. 7.

At these layer boundaries, both the primary aluminum matrix and the needle-shaped silicon undergo coarsening, sometimes to the point of silicon crystal growth, as shown in Fig. 7. It is to be noted that even with the coarsening effects, the secondary dendrite arm spacing observed in powder-fed deposited aluminum–silicon alloys of <10 μm is still significantly smaller than as cast microstructures, which could be higher than 100 μm. This refinement is one of the advantages that powder-fed deposition and other AM processes bring to the table compared to conventional cast and forge operations. The refined grain structures lead to increased yield strength and decreased ductility. With these smaller grain sizes, hardness and wear resistance are also observed to increase.

Fig. 7 Optical image of the as polished microstructure of 4047 Al (hypoeutectic) deposited on 2024 Al using BPD

Powder Bed Processes

While powder-fed deposition has exhibited significant capability in processing a few aluminum alloys, it is still hampered by the issues associated with high reflectivity, thermal conductivity, large interaction volumes, and slow process speed that are inherent to this process–material combination. Powder bed-based AM negates some of these issues associated with powder-fed deposition by employing smaller laser spot sizes and high-speed processing to create small interaction volumes. This enables powder bed deposition to bring even higher refinement to the processing of aluminum silicon alloys. This is validated by powder bed deposition’s ability to process even pure aluminum, which is the worst possible combination of high reflectivity and high conductivity.^[37] Powder-fed deposition, though, retains its advantages of repairability, on-demand energy and material input, and localized spatial tailoring of properties. In addition, as powder-fed deposition systems possess large laser spot sizes, the volume of material deposited can be high, while the same is not possible in powder bed deposition that is restricted to small layer thicknesses and spot sizes. As a comparison, while powder-fed deposition was able to deposit aluminum alloys at $28 \text{ mm}^3/\text{s}$,^[34] the highest volumes achieved even by atypical high power selective laser melting have peaked at $21 \text{ mm}^3/\text{s}$.^[38]

Researchers involved with powder bed deposition have been able to expand the raw material selection of this process by expanding the alloying elements for the powder feedstock. The small interaction volumes and the extremely high scan speeds minimize the significance of material reflectivity and absorptivity, thereby increasing the retained energy density per unit volume per unit mass. While these advantages have enabled researchers to

extensively utilize powder bed systems to process a wide range of aluminum alloys, the powder bed process is still plagued by issues associated with rapid solidification. As previously discussed, the large thermal gradients and small interaction volumes amplify some detrimental effects such as gas entrapment, shrinkage porosity, keyhole mode, residual stresses, distortion, delamination, and cracking failure to a much higher extent compared to powder-fed processes.

It is to be noted that even though AM processes have been gaining popularity, the supply chain necessary to manufacture the powder feedstock is not extensive and has been mostly restricted to research facilities. It is the authors’ contention that the availability of a wide range of feedstock powders and the supply chains to manufacture them will tilt the economics to favor additive processes over their traditional cousins. There exist few vendors and associated monopolistic market strategies have limited the availability and increased the expense of even commonly sought after powders in the category of steels, nickel alloys, and titanium alloys. If these issues could be compensated for, both powder bed and powder-fed processes would be well served, and their adoption and implementation would only increase. While AM’s adoption has been limited to components where economics are not the primary concern, creating the feedstock and economizing their use will embolden researchers and engineers to start designing for AM processes and ultimately increase their applicability. This is especially true in the case of aluminum and its alloys that are difficult to source in the desired alloy purity and particle size while exhibiting economics compared to raw material in bar form.

To compensate for these supply chain limitations, researchers have been blending, mixing, and ball milling small combinations of available powder stock to achieve their target raw materials. Surveying the existing literature

indicated that the popular existing powder feedstock was aluminum–silicon alloys. While some literature indicated that pure aluminum powder is a feasible powder bed feedstock,^[37] the dominant research interests indicate that aluminum–silicon alloys (and minor variations) are the favored choice. This can be attributed to the increased light absorptivity that silicon brings to this mixture. Some of the popular choices of materials involving pre-alloyed powders include AlSi10Mg,^[21,39–41] AlSi7Mg0.3,^[42] and AlSi12.^[43] By means of blending elemental powders with aluminum feedstock materials such as Al–Si–Ni alloy,^[44] composites such as Al–Al₂O₃^[45] and Al–Si50^[46] have been fabricated. Atypical examples of powders have also been created, where researchers employed in-house gas atomization and fabricated novel alloys by adding rare elements to dramatically alter the microstructures. The addition of Sc and Zr to Al6.2Mg alloy created a unique alloy with heightened electrochemical corrosion resistance.^[47] Advanced materials such as quasi-crystal composites were fabricated by blending pure aluminum with Al–Cu–Fe–Cr quasi-crystal powders.^[48]

Irrespective of the powder employed, the infancy of processing aluminum alloys using AM processes has created a need for the detailed characterization of the mechanical and microstructural properties of these materials. The lack of detailed process maps has also led to scenarios of detrimental effects such as porosity and other defect mechanisms occurring during AM of aluminum alloys. All of these demand thorough investigations with researchers actively identifying and solving all the issues associated with additive manufacture of aluminum alloys. In rare cases, the issue might not be associated with the process of material alone, but the causality could be the combination. Effects such as residual stress buildup are indicative of the failure of that particular process and material combination. Some of this research including work compiled by Aboulkhair et al.^[39] investigated approaches to mitigate porosity and obtain near dense parts. Their extensive work quantifies the relationship between hatch spacing and scan speed. The research shows the AM community that the amount of energy dictates the primary pore formation mechanism. As shown in Fig. 8, the need is to minimize the occurrence of keyhole-mode porosity formation. The rationale in the AM community has always favored avoiding this keyhole formation, which causes materials to rapidly evaporate and drastically changes the localized chemical composition, thereby creating zones of detrimental mechanical and microstructural properties. This keyhole mode porosity formation also causes inhomogeneity in the chemistry of the fabricated part.

For flaw free interlayer bonding, the need of the hour is sufficient energy not just to change the phase of the material but also to promote wettability. The scan speed involved in powder bed processes affects this energy and by extension the stability of the melt pool.^[40] In cases of instability, defects such as balling appear. These defects

Fig. 8 Relationship between hatch spacing and scan speed and the primary pore formation mechanism for AlSi10Mg alloys^[39]

can lead to pores and weak interlayer bonds. While it may seem like this scenario can be avoided by excess energy input, care has to be taken to avoid the aforementioned keyhole mode.^[39] In some cases, the keyhole mode also creates spatter of the melt pool, thereby creating surface defects. Excess energy input creates a superheated melt zone that promotes the oxidation of these aluminum alloys, which already exhibit extraordinary affinity for oxygen. Any oxide formation will detrimentally affect wettability.^[47] The ideal process plan should avoid all these scenarios. These causal relationships between the defect formation and process parameters were also identified by many researchers when investigating other aluminum alloys.^[38,42,44,49]

In comparison with powder-fed processes, while powder bed processes do not exhibit the problems associated with extreme reflectivity, some researchers have observed that substrate heating employed during powder bed fabrication benefitted the end product.^[50] When substrate heating was employed, the average temperature of material increased leading to minimized residual stresses.^[42,44] It was theorized that when the substrate temperature increases, the reflectivity of the material reduces. This enables more incident energy to be absorbed yielding heightened melt pool and process stability. Another consideration of importance is the chemistry of the alloys and the influence of the constituent elements on solidification. For example, work done by Kimura et al. focused on varying the silicon weight percentage of aluminum–silicon alloys from 0 to 20 wt.%. This changing alloy composition demands the development of unique process parameters for each alloy powder. The difference in the microstructure produced by the various combinations can be observed in Fig. 9. Low silicon quantities are soluble in aluminum, and its increasing weight percentages yield hypoeutectic, eutectic, and hypereutectic microstructures, all of which can be observed by the change

Fig. 9 Optical microscopy of the XY-planes (denoted as -1) and Z-planes (denoted as -2) of etched Al-xSi powder bed specimens fabricated using ideal process parameters. The various images represent the varying silicon percentages namely (a) Aluminum with 0% Silicon, (b) Aluminum with 1% Silicon, (c) Aluminum with 4% Silicon, (d) Aluminum with 7% Silicon, (e) Aluminum with 10% Silicon, (f) Aluminum with 12% Silicon, and (g) Aluminum with 20% Silicon^[37]

in the images in Fig. 9. Pure aluminum material indicates shrinkage porosity, which progresses to low silicon alloys (<1%). At this low silicon content, when silicon is soluble in aluminum, solidification cracks are formed during crystallization, which are the result of the high residual stresses in this alloy process combination. With the increase in silicon content, a change from primary aluminum to primary silicon can be observed, which is indicated by the change in the color of the melt pool boundaries in images (d-1) and (g-2). It is also to be noted that unlike conventional casting techniques where the eutectic point is at 12% silicon content, the rapid cooling produced by AM techniques shifts this to a higher silicon content.^[51–53]

The difference in the microstructures from the powder-fed processing in Fig. 7 to the powder bed process in Fig. 10 is readily apparent. In the case of powder bed processes, a supersaturated solution of aluminum–silicon forms surrounded by a fine intercellular network of silicon. The cells are exceedingly fine and can be sized in the nanometer scale. Typically, during conventional casting, post process heat treatment is a means of grain refinement, age hardening, and improvement of mechanical

properties. During heat treatment of conventionally cast materials, the grain types do not change, but the grain size could become significantly refined. In powder bed processes, the outcome is considerably different. As observed in Fig. 10, the matrix, which is a supersaturated solution of aluminum and silicon, is active and changes considerably during the heat treatment process. This is better illustrated in research quantified by Li et al, where the small silicon particles from the as built structure converge to form the large silicon crystal growth after undergoing heat treatment. During this heat treatment, the excess silicon from supersaturated aluminum–silicon solution is expelled and coalesces into silicon growth that resembles globules as observed in Fig. 11.^[43] This transformation in microstructures heavily alters mechanical properties and performance. The high yield strength that might result from the ultrafine microstructures could be lost during this heat treatment transformation.

Like other AM processes, owing to the layer-by-layer build schema, powder bed processes also exhibit directional solidification. This directional solidification imparts an inherent anisotropy to powder bed components.

Fig. 10 Electron microscopy of (a) horizontal cross section of a powder bed specimen and (b) vertical cross section of a powder bed specimen^[42]

Fig. 11 Electron microscopy of microstructure of the Al-12Si alloy. (a) As-fabricated with two distinct regions. Coarsening of silicon (light gray particles) was observed with solution treatment at 500°C for (b) 15 min, (c) 30 min, (d) 2 h, and (e) 4 h^[43]

Also like other AM processes, the mechanical properties that powder bed parts exhibit are highly dependent on the process parameters and the values employed by them. This is reflected in many studies by researchers and is clearly observed in the comprehensive study performed by Hitzler et al.^[55] They found that the modulus, yield strength, ultimate strength, elongation at failure, and Poisson's ratio varied with build direction, orientation, and scan strategy, details of which can be observed in Fig. 11 and Table 1. These and other factors, like the gas flow direction, all contribute to the directionality of the cooling. While it was observed that the powder bed components performed better than their conventional counterparts,

powder bed AM components exhibited higher variation in their performance. These variations can be traced back to the components location, scan strategy, and orientation during construction in the powder bed. This was further confirmed by data generated by Kempen et al. who noticed a difference in the ductility and impact toughness.^[41] It is to be noted that the properties discussed in this section are for built powder bed parts without any post process heat treatment. As discussed before, heat treatment alters the microstructures and therefore the mechanical properties of aluminum alloys that could be warranted based on the application and the alloy's ability to be bettered through post process treatments.^[43]

**Fig. 12** Assessment of the mechanical properties of AlSi10Mg and their relation to build direction, orientation, and scan speed^[55]

While the variation in properties can be mostly attributed to the process parameters, powder bed parts are known to include porosity which could be another factor that detrimentally contributes to the mechanical properties. While many researchers have employed post-process treatments such as hot isostatic pressing to minimize the porosity and create near dense parts, the problem still persists. The pores' greatest effect is felt on fatigue life of the components manufactured using powder bed processes. Researchers investigating fatigue life observed that nearly every failure was initiated at a surface imperfection or a

subsurface pore.^[54] To keep their effects low, the general recommendation is to reach at least 99% density of the components under investigation. Brandl et al. also noticed a correlation between the fatigue resistance and the ultimate tensile strength. Therefore, they theorize that any treatment that can improve the ultimate tensile strength will also favorably improve fatigue performance.^[54]

The final major performance metric that has been comprehensively quantified for powder bed manufactured aluminum alloys is their wear resistance. Wear resistance is of particular importance to the aerospace, automobile

and electronics packaging industry who investigate and utilize hyper eutectic alloys with silicon content exceeding 25%.^[56] These alloys are difficult to subtractive manufacture and therefore benefit in many ways than one by their use with powder bed processes. The ultrafine microstructures that are a hallmark of powder bed processes are observed to improve wear resistance.^[57] The powder bed processes were also observed to achieve better dispersion of silicon which seems to directly improve wear characteristics. In this scenario as well, care must be taken to ensure the occurrence of minimal porosity. Kang et al, have also reported the use of employing static magnetism to achieve tailored microstructures that also tailor wear resistance.^[57] The ultrafine microstructure also has favorable properties when experiencing cavitation erosion. While the erosion is high during inception, it quickly slows down substantially when compared to wrought AlSi10Mg.^[58] All of the investigations validate the fact that powder bed processes offer significant material flexibility and performance improvements over conventional aluminum manufacturing processes.

Other AM Processes Manufacturing Aluminum Parts

While the scope of their aluminum alloy research is not as extensive as the powder processes of the preceding sections, UC, GMAW, and micro droplet deposition are also viable AM processes for these materials. As it is a sheet lamination process, UC undergoes solid-state bonding to build up in a layer-by-layer manner just as other AM processes.^[59] Unlike other AM processes, the effect of anisotropy is more prevalent in parts manufactured using UC. As ascertained by Sridharan et al.,^[60] the localized strain from UC is theorized to form micro voids at the interfaces between layers. When loads perpendicular to the consolidation path are applied, it is anticipated that these voids coalesce, thereby initiating and propagating failure. To improve the mechanical properties, heat treatment has been identified as a viable option. Successful heat treatment was observed to promote grain growth across the layer boundaries, which in turn was noticed to moderately improve mechanical performance.^[61] In rare cases, researchers have been developing novel AM technologies like micro droplet deposition capable of processing aluminum alloys.^[62] While it shows promise, the process is still under development and shows potential to achieve material performance comparable to wrought alloys.^[63]

The final process under discussion is GMAW which is capable of producing aluminum alloys components to 99% density. Some advantages of this process include the ability to deposit at extremely high speeds^[64] and the ability to deposit even highly reflective alloys. The principle of energy input in a GMAW process is not contingent on the absorptivity of light as in the powder AM processes discussed. This process is also capable of

producing near isotropy in its deposited components and has the advantage of using a near endless material supply chain developed as part of the weld process development. However, this process exhibits lower cooling rates compared to powder-based AM processes and therefore cannot achieve the grain refinement of those processes. Control over geometry, density, and solidification during fabrication is reliant on the chemistry of the filler material employed. Addition of silicon has been identified to be beneficial for minimizing porosity in aluminum alloys.^[65] GMAW was identified to be capable of producing material with mechanical properties comparable to its wrought counterparts.^[65]

CONCLUSIONS

A number of researchers have successfully processed aluminum and its alloys using AM. Extensive material published in the area of PBD indicates that it is not just a viable process, but the notion of leveraging its advantages has proven attractive to many researchers. UC has also had research interest, while it is only in the recent past that PFD has been shown as a viable process for aluminum alloys. While few have successfully demonstrated the capability with pure aluminum, a significant number of these successes have involved aluminum-silicon alloys or the same with minor elemental variations. Many researchers have even tried to process aluminum composites and demonstrate functional grading. Researchers have fabricated pure aluminum and alumina composites using selective laser melting, while others have fabricated selective laser melt process parts using aluminum and high silicon alloys and even some aluminum composites. Literature exists on fabrication of a multitude of aluminum silicon alloys; some of them to near full density by identifying ideal process parameters. Researchers have also processed and characterized a number of common welding filaments using a GMAW-based 3D printing process.

A common theme among most of the aluminum alloys that have been successfully processed by AM techniques has been inclusion of silicon. It is theorized that this addition brings improved absorptivity and improves flowability, which are of particular importance when lasers are employed. The microstructures produced by powder-based processes have been observed to be highly refined as compared casting and other conventional operations. In the case of powder bed processes, this fine microstructure has been observed to be in cellular dendritic in morphology. The fine microstructures when paired with the alloying elements under investigation have yielded excellent mechanical properties and improved wear, fatigue, and corrosion characteristics of the powder bed fabricated parts. Even parts made by UC and the novel micro droplet deposition have yielded components whose mechanical performance match and in cases beat that obtained by their wrought

counterparts. While the energy source of the GMAW is not as focused as the other processes discussed in this article and therefore cannot achieve the same degree of microstructural refinement, it has demonstrated significant ability in processing aluminum alloys. With its long and well-established reputation as a joining process, it also has the most developed material supply chain and the widest range of process-able materials.

The aluminum–silicon alloys discussed in this article have spanned the gamut from hypoeutectic to eutectic, and into the high hypereutectic combinations. Each brings its own unique material dynamics and solidification mechanics that the AM processes involved have handled with varying degrees of success. The high cooling rates of these processes have been observed to shift the eutectic point to higher silicon concentrations. These and the ability to target and create metastable microstructures could expand these alloys' applicability to a wide range of industries. While their demand is currently extensive in the aerospace, automobile, and packaging industries, with the relevant and necessary postprocess treatments, the authors see them being employed in other applications that demand high strength-to-weight ratios and thermal and electrical conductivities. With the supply chains needed to tailor and economically manufacture feedstock steadily under improvement, the authors only see increased research scope, and industrial adoption in the future of aluminum alloys and their associated manufacturing techniques.

Aerospace Fasteners: Use in Structural Applications

George Nadim Melhem

University of New South Wales, Australia, Sydney, New South Wales, Australia

Abstract

Aircraft components need to be selected and manufactured to adequately combat the environment, temperature, loading, compatibility, and so on. When structural materials such as aluminum alloys or fiber-reinforced polymer composites need to be joined in aircraft, the selection of fasteners, bolts, rivets, adhesives, and other methods need to be quantitatively assessed in order that the correct design for the component and joining method is identified. There is a variety of fasteners, bolts, and rivets, made using a variety of materials. Aluminum rivets are often used to join aluminum components in an aircraft. Rivets do not perform well under tension loading, but perform better in shear, thus limiting the application specifically for these purposes. Bolts are designed to clamp material together, and even though the bolt may be adequate to support a particular structure and load requirement, consideration must also be given to the modulus of elasticity and stiffness of the components that are being clamped together. Therefore, an understanding of each of the materials being clamped or joined together is necessary. Bolts manufactured from steel, for instance, have coatings applied in order to help protect them from corrosion. The use of composites translates to a reduced number of rivets and fasteners to be used. Drilling of holes into composites to insert fasteners poses many challenges because the fibers are damaged, a region of high stress concentration may be formed, and the hole is a site for the ingress of water or moisture. The insertion of aluminum fasteners or the contact of aluminum components with carbon fibers creates galvanic corrosion due to the large difference in electrical potential. Titanium alloy (Ti-6Al-4V) is a typical fastener where there is composite joining due to its better compatibility (elimination of galvanic corrosion) and increased strength properties. Substitution of rivets and fasteners for welding is also on the increase in aircraft because laser beam welding (LBW) and friction stir welding both reduce cracking, porosity, and better properties achieved due to deeper penetration, and reduce the heat-affected zone which would typically be undesirable with conventional arc welding such as metal inert gas and tungsten inert gas welding. The shear and compressive stresses are increased, and fatigue cracking, weight, and cost are also reduced as a result of LBW, including the elimination of stresses and corrosion associated with rivets and the elimination of adhesives. Dissimilar metals such as the 7000 series and the 2000 series can be joined with a filler metal compatible to both metals to mitigate galvanic corrosion.

Keywords: Aircraft; Bolts; Galvanic corrosion; Rivets.

REQUIREMENTS TO PUSH THE ENVELOPE IN MATERIALS

A myriad of factors must be considered when designing aircraft, with some of the most important being structural safety, longevity, weight, fuel efficiency, and cost. An aerospace engineer can potentially choose from over 120,000 different materials for use in the airframe or engine. However, typically less than 100 different materials are suitable for most aerospace structures.^[35] The main reason for this limited number is due to the stringent property requirements for aircraft material to be lightweight, stiff, strong, fatigue resistant, toughness, damage tolerant, durable, easy to manufacture, and cost-effective. The majority of

the materials are therefore ruled out as a result of these mandatory properties.

Aircraft structural materials used in major components such as the fuselage, wings, landing gear, and empennage are subject to a range of loading/forces. For example, an aircraft fuselage is subjected to various forces including compression, tension, bending torsion and pressurization as it is carrying the entire payload. As another example, the upper surface of an aircraft wing is subjected to compression and the lower surface to tension during flight. Figure 1 shows that 2024 and 7075 aluminum alloys are used in the upper wing skins and stringers as they have a good combination of the following properties: compressive yield strength, modulus, fatigue, fracture toughness,

Fig. 1 Materials selection for structural members of a typical passenger aircraft^[39]

fatigue crack growth, and corrosion. The most commonly used aircraft structural materials are high-strength aluminum alloys, titanium alloys, and carbon fiber-reinforced polymer composites.

AEROSPACE FASTENERS: USE IN STRUCTURAL APPLICATIONS

The variables involved in the selection of fasteners to join aircraft components can be immense due to the assembly of an extremely large number of parts. Because aircraft are subjected to a variety of loads and design constraints, this necessitates a large number of components made of different materials/strengths. With the advancement of the aircraft and its design, consideration must be given to design for a myriad of metals and composites combined.

The challenges faced in aircraft construction range from incorrect design or lack of available information/knowledge/history, environmental factors, temperature, initial preload, fatigue, vibration, incorrect maintenance scheduling or incomplete/incorrect maintenance, undetected corrosion hidden beneath complex joints that are not easily accessible or exposed to rain for washout of debris, dissimilar materials

being joined to one another (metal/metal, metal/composite), incorrect heat treatment of metals or incorrect construction of composites (fiber orientation or manufacturing flaws), pilots incorrectly maneuvering aircraft and subjecting materials to stresses beyond their design capabilities, bird strike damage, lightning strikes, and so on.

There are many variables for the design engineer to consider before deciding upon the best means for joining structural components. The most common joining methods are adhesive bonding and mechanical fasteners such as bolts, rivets, and screws. Bolts can be selected from a variety of grades such as steel (e.g., carbon steel, stainless steel). Titanium and aluminum are also used as fasteners, although aluminum is not widely used due to its low yield stress and susceptibility to corrosion. Titanium (Ti-6Al-4V) fasteners are commonly used where diameters are less than ~19 mm, whereas many larger diameter fasteners are made of steel.

Steel is used for fasteners in landing gears, wing root, and wing attachments due to its very high strength, stiffness, and fatigue-resistant properties. Rivets are mostly manufactured from titanium, A286 stainless steel, and plain carbon steels. The head is easily formed by bucking, and they will not crack as they have good cold-forming properties. Most rivets have universal heads, but other typical head

Fig. 2 Typical rivet heads—the United States^[4]

designs are shown in Fig. 2. Rivets should not be used for joining composites as they expand into an interference fit, and this may cause delamination damage around the hole.^[4] Table 1 lists the various types of fasteners, their grades, and their recommended application with certain materials for galvanic compatibility.

Huckbolts as shown in Fig. 3 have their stem broken in the position of the notch. These bolts are available in aluminum, stainless steel, and carbon steel. Generally, aircraft rivets are of aluminum alloy grade such as 5056, 2117, 2017, 2024, and 1100.

High-shear pin rivets (Fig. 4) are made from aluminum, stainless steel, titanium, or carbon steels. However, this type of rivet is only used for shear-loading purposes. Lightweight grooved proportioned lockbolt (Fig. 5) is manufactured with a titanium shank which has a high-shear capability and is typically used in joining composite materials. The extra-large sizes made for the heads and collars have been designed intentionally in this manner in order to minimize stresses on the composite material.

FASTENERS USED FOR THE ASSEMBLY OF AIRCRAFT COMPONENTS

Blind fasteners differ from rivets in that only one side is easy to access.^[26] Threaded fasteners are easily removed even after assembly without any damage to the fastener. Pin fasteners may be either tubular or solid and are used primarily where shear is the dominant load. Most aircraft structures require fasteners that may be used in combination with adhesives. Most of the above-mentioned fasteners can be used in composite joints such as rivets, pins, bolts, and blind fasteners (see Table 1).

THREADED FASTENER DESIGN FOR AIRCRAFT

Fasteners can generally be categorized into two main types: (1) tensioned fasteners with a threaded nut are designated as bolts, and (2) the other type has a dependence upon the bolt shank tensile strength which is applied to clamp the material

Table 1 Applications of various composite materials with various fastener types^[26]

Fastener type	Fastener material	Surface coating	Suggested application			
			Epoxy/graphite composite	Kevlar	Fiberglass	Honeycomb
Blind rivets ^a	5056 aluminum	None	Not recommended ^b	Excellent ^b	Excellent ^b	^c
	Monel	None	Good ^b	Excellent ^b	Excellent ^b	^c
	A-286	Passivated	Good ^b	Excellent ^b	Excellent ^b	^c
Blind bolts ^d	A-286	Passivated	Excellent ^b	Excellent ^b	Excellent	^c
	Alloy steel	Cadmium	Not recommended ^b	Excellent ^b	Excellent	^c
Pull-type lockbolts	Titanium	None	Excellent ^e	Excellent ^f	Excellent ^f	Good or not recommended ^g
Stump-type lockbolts	Titanium	None	Excellent ^e	Excellent ^f	Excellent ^f	Good or not recommended ^g
Asp fasteners	Alloy steel	Cadmium/nickel	Good ^h	Excellent	Excellent	Excellent
Pull-type lockbolts	7075 Aluminum	Anodized	Not recommended	Excellent	Excellent	Not recommended

^aBlind rivets with controlled shank expansion.

^bMetallic structure on the backside.^[26]

^cPerformance in honeycomb should be substantiated by installation testing.

^dBlind bolts are not shank expanding.

^eUse flanged titanium collar.

^fFasteners can be used with flanged titanium collars or standard aluminum collars.

^gDepending on the fastener design, check with manufacturer.

^hNickel-plated Asp only.

**Fig. 3** Huckbolt fastener^[4]**Fig. 4** Hi-Shear installation^[4]

together and to take advantage of the friction that exists between the two mating surfaces, hence not depending upon the shank properties. The other type depends purely upon the bolt shank strength. The most commonly used standards for bolt fasteners are American National, Unified, or the International System of Units (SI) (ISO metric) as shown in Fig. 6.^[25,26] ISO metric thread is the dominant standard (IS 4218-1976—in four parts) applied to threads. The designation for a coarse thread is by using the letter “M” followed by the nominal diameter of the bolt in mm, i.e., M6. The fine thread is also designated as the coarse thread, but with the additional introduction of the pitch in mm followed by the symbol “×,” i.e., M6 × 0.75.^[6,25]

When the fastener is tightened, there are compressive stresses that are exerted upon the respective faces of the material directly in contact with the bolt head under surface,

**Fig. 5** The parts are pulled tightly together with the flanged collar over the pin. Collar locks in grooves and the pin breaks away^[4]

and also compressive stresses imposed upon the surface of the nut/washer in touch with the material being clamped. The torque is dependent upon the quality of the thread, plating/coating on fastener, lubrication, and the applied pressure. While it may be more direct to calculate the stiffness of fasteners, it becomes more complex when calculating the stiffness of the mating materials that need to be clamped together. The stiffness of a bolt is given as follows:

$$k_b = A \cdot E_b / l,$$

where k_b is the stiffness of the bolt, A is the nominal area, E_b is Young's modulus of the bolt material, and l is the total thickness of the members joined as shown in Fig. 7. The stiffness of the gasket and the members also need to be determined; however, because the cone compressive area extends as shown in Fig. 7, it is difficult to determine the member's stiffness.

The method to manufacture threads may be performed by one of two methods: cutting or rolling. Cutting is achieved via thread cutting machines that are called “screw” machines. Rolling is a forming method of bar stock into a threaded bolt. The advantages of bolts manufactured

Fig. 6 Thread illustrating American National or Unified and SI^[25]

Fig. 7 Cone showing the compressive load area^[25]

from rolled bar as opposed to cutting are compressive residual stresses, which are introduced as a result of cold forming and rolling to achieve better mechanical properties in the threads such as improved strength and fatigue resistance. The cold forming creates blunting or radii at the root and the crest of the thread, thus reducing any stress concentrations. Bar stock are taken from forgings that have directional flow of lines, and the profile is selected so that these lines are parallel to the tensile loads and perpendicular to the shear loads.

MODES OF FAILURE IN BOLTS

Approximately 65% of bolt failures occur at the nut and bolt thread interface, at the thread ends (20%), or (15%)

under the bolt heads.^[25] These are due to the design of the bolts which inherently have stress raisers. If the design includes the fatigue stress concentration factor, then the failure can be avoided. For instance, if we refer to Fig. 8 to increase the capacity for the bolt to absorb shock, the design needs to include a rounded groove just after the threaded section of the shank, and it should be no greater than the diameter of the smallest diameter of the thread. Ideally, the most favorable bolt design would have stress levels being equally distributed at various cross sections.^[6]

Two modes of failure occur in bolts, and these are tensile in bolts and shear of the thread on the inside of the nut. Under tension, the bolt fails along the plane in the area of stress being applied. The tensile area of an unthreaded rod has been tested on threaded rods according to ISO.^[6] for comparative purposes. The diameters of the unthreaded rods such as the minor diameter (d_3) plus the pitch diameter (d_2) divided by two have the same tensile strength as that of the threaded rods. This is the region that is calculated for the purposes of bolt tensile strengths. The crests and roots of a thread may be either round or flat, and the reason for this is to minimize the stress levels in threads. Bolts have either coarse or fine threads, and the function of coarse threads is to reduce the static loads of the bolts while in service. Coarse threaded bolts do not

Fig. 8 Bolt design for increased shock absorption. d_1 = major diameter; $d_{\text{crest}} = d_1$; d_2 = pitch diameter; d_3 = smallest diameter; p = pitch (thread load applied equivalent to d_2)^[25]

Fig. 9 Bolt and nut failure^[25]

easily seize while being tightened. Fine threads are stronger than coarse threaded bolts when alternating loads are imposed and are suitable for the components in service under dynamic loading and vibration. There is a larger effort or resistance in unscrewing fine threaded bolts.^[6]

The nut and bolt both have a load acting upon them as shown in Fig. 9, where the failure occurs at the root diameter. The thread shear area in a bolt is smaller than that in a nut, and for this reason, it has less material to contend with the shear forces and fails first. If the design stipulates that the bolt thread must not fail, then a safe height of the nut is calculated in order that shear failure is eliminated at the bolt thread.

The typical bolt design includes the consideration for a safety factor and material to be used. As a rule of thumb only, threaded fasteners, for instance, require a certain length of full thread engagement, and for aluminum, it is approximately two times the diameter of the fastener and one time the diameter for steel. The spacing between the bolts should not be more than six times the diameter.

PRELOADING OF BOLTS

When the nut is tightened after some free turning, the bolt is stretched and the bolt is placed in tension, and this is termed the preload. The preloading is based upon the torque being applied so that the bolt is stressed to 90% of the proof strength required for static loading and 75% of the proof loading for dynamic loading. If the tension of the bolt is maintained in the elastic range, then a clamping force is applied on the member joints, thus creating what is defined as a preload.^[25] The members subjected to compressive forces do so with the same magnitude that the bolt experiences the tensile force, that is if the members' stiffness is not ignored, and the members' stiffness needs to be higher than that of the bolt. The level of stretching in the bolt should be higher than the level of compressive movement of the members. That is, when the members joined have an applied load by torquing, the members are compressed together and clamped. Preloading assures a reduction in fluctuating stresses (remains inside the fatigue limit) and tighter joints, and minimizes or eliminates leaking.^[6,25]

EFFECT OF PLATING ON FASTENERS AT VARIOUS TEMPERATURES

Steel or carbon fasteners have good strength up to 55 ksi or 379 MPa, but poor corrosion resistance and high density and weight. Carbon steel can be surface treated with either zinc or phosphate to resist corrosion. Stainless steel fasteners are also commonly used for aerospace applications, and have excellent corrosion resistance and require no surface treatment. Their strengths range from 70 ksi or 482 MPa up to 220 ksi or 1516 MPa.^[4]

Cadmium plating is the most applied plating for aerospace fasteners, and it is baked at a controlled temperature/time to avoid hydrogen embrittlement. As stated prior, aluminum fasteners are not commonly used in aircraft. The main limitations of aluminum are strength and temperature capabilities compared to other materials such as steel alloys.

USE OF FASTENERS AND RIVETS IN THE CONSTRUCTION OF COMPOSITES

Rivets are not typically used for composites, because they expand while being installed with a rivet gun, and this can introduce delamination. The structural attachment design process is a major challenge in developing composite structures.^[37] The bolted joint is the weakest link in the structure.^[47] It is well documented that there is a reduction in the loading capacity of composites, because complicated stress fields adjacent to the holes occur; hence, the evaluation of failures in the joints is extremely challenging.^[23,46] Designing for composite mechanical fastening joints has been broadly based upon experimental data. Many groups have developed testing methods for mechanically fastened joints such as the National Aeronautical Space Administration and the Federal Aviation and Administration.

The literature shows that both glass and carbon epoxy composites were among the most widely studied materials, and that the experiments focused on the clearance between the hole and the pin, the degree of lateral clamping force exerted by pin or bolt, the stacking sequence, and the geometric properties.^[41] Some experiments have concluded that the larger the plate or the greater the width of the composite to the diameter of bolt, the greater is the bearing strength. Also, whether bearing strength increases with increasing preload and bearing strength is also dependent on the ply stacking sequence. Camanho and Matthews^[8] concluded in his review of the literature on fastened joints that the areas of research in stress analysis and strength predictions of mechanically fastened joints were not universally agreed upon as to how to appropriately predict the type of failure mode.

Failure modes for fastener joints are shown in Fig. 10.^[11,24] Some important bearing capability considerations are lateral constraint, single shear lap joints, and countersunk holes. Lateral constraint helps to reduce the buckling fibers

Fig. 10 Failure modes of fastener joints in composite plates: (a) net tension; (b) shear-out; (c) bearing failure^[11,41,47]

in the composite, thus providing a higher bearing stress.^[14] There is a decreased bearing strength when there are countersunk holes because complex three-dimensional stress fields exist in the vicinity of the hole, and this is much more pronounced than that for flat surface-aligned holes.^[12]

Since composites are brittle, and unlike metals such as aluminum which is typically used in aircraft, they show little or no signs of deformation. It is clear then that underneath the composite surface layer, there could be instances of damage where the surface has had some impact upon it. If there is damage beneath the surface, then there could be extended periods of time whereby this damage is not detected at all, and eventually leads to failure.

The restrictions mentioned previously in this section with regard to mechanical fastening in composites, combined with degradation of composites at high temperatures,^[10,38] the hygrothermal effects in composites makes the picture even more complex! The field in composites, in particular with respect to mechanically fastened joints, requires yet much more research and study in a more systematic way before any real confidence can be stipulated in the design of aircraft assembly.

Of major concern reported throughout the literature is that fasteners provide a chief conduction pathway for lightning currents (up to 200,000 amps in fasteners), which stem from the skin of the aircraft and make its way into the ribs and spars and poor fasteners arcing or sparking from lightning strikes. Figure 11 shows a fastener sparking. The greatest fear is due to fastener arcing; this could cause lightning near the composite fuel tank as this may cause hot debris (gas or particle) to be ejected due to the fastener

being struck and could lodge itself into the fuel tank creating a catastrophe. To protect against lightning current, one method is to use metal (aluminum, copper, or bronze) mesh near the surface of the composite while being manufactured. Commonly, the mesh used to cover the composite is on the surface and is called the bolt-line. The bolt-line mesh increases the area of metal for each fastener, thereby enhancing electrical continuity/current dispersion and reducing the risk of the fastener sparking. Secondary structures such as tail cones, wing tips, and flight controls generally do not have the quantity of fasteners to enable transfer of lightning currents.^[44] This results in further damage to material in the vicinity including other fasteners.

Another source of problem occurs when holes are drilled into the composite structure, and the holes actually create a barrier for the flowing current throughout the composite structure and thus serve as a site for an increased current path.^[44] Defects may be present as a result of the drilling such as fiber pullout and exit delamination. These defects are denoted as machining-induced effects.

Fasteners for composites ideally should have large heads in order that the loads are distributed over larger areas to avoid crushing. Damage to the composite can be done if the correct drill bits are not used. When the cutting tool wears, more surface chipping, more fiber fractures, fiber pullout, and exit delamination.^[20] If the hole is too large as mentioned previously, then this will cause oscillating shear loads or fretting, and to overcome this problem, a simple but not highly recommended procedure is to bond the fasteners in place with adhesives. When composites are cut, their fibers are exposed.

Fig. 11 Sparking of fastener

GALVANIC CORROSION DUE TO ALUMINUM FASTENER-COMPOSITE CONTACT

The corrosion of aluminum occurs when it is in contact with carbon fiber-reinforced composites. Tests with salt sprays or with natural environment illustrate that corrosion is harsh.^[7] In an aircraft, the carbon composite control surfaces such as the aileron and elevator may have aluminum hinge fittings connected to them, thus creating a strong potential for galvanic corrosion. Therefore, in aircraft the carbon composite is cathodic, and it is in contact with the smaller components such as metal bolts and rivets, for instance, and are anodic. The small anode (aluminum rivet/bolt/fastener/nut) to large cathode (carbon composite) accelerates the corrosion. Therefore, aluminum fasteners connecting carbon composite must be avoided if the fibers are in direct contact with aluminum, by using titanium (closer to graphite in the electrochemical series). Titanium alloy (Ti-6Al-4V) is the typical fastener that is used for carbon fiber composites. Another method to eliminate galvanic corrosion is to use glass fabric electrical insulation layer between aluminum and carbon fiber composite.^[9] Boeing 777 utilized an aluminum splice channel in order to avoid the direct contact between the carbon composite floor beam and the primary structural frame.^[29]

FASTENER RIVETS AND BOLTS SUBSTITUTED FOR WELDING OF METALS IN AIRCRAFT

LBW utilizes a solid-state or gas laser as a high-power density to melt locally a filler wire which is situated between the two work pieces to be joined. Shielding gas such as argon mixed with helium provides a good mix to shield the fusion joint from impurities in the air that may enter. This eliminates or reduces hot cracking and porosity, which are some of the undesirables of LBW. The reduction in hot cracking can be achieved by reducing the hydrogen solubility in the HAZ, and certain alloys can be chosen to reduce solidification cracking also.^[36] Other disadvantages include reduced strength in the HAZ. LBW was used in the A380 to attach stringers to the bottom section of the fuselage skins. The process involves welding approximately 8 m in about a minute, and this has been in use since 2001 to connect the lower skins of the fuselage in the A318.^[42] Welding decreases the weight when substituted for rivets but increases the shear and compressive stresses as opposed to using rivets. The reduction of the overall weight of the aircraft actually translates into approximately 10% of weight savings in stringer panels used below the main deck floor in the A380.^[40]

This removes not only rivets but also the possibility of corrosion and many other adverse properties including fatigue cracking that have been the result of rivets. The stringer and skin connection are not riveted as a result of the LWB taking its place, and it is performed at much reduced

construction costs. Laser welding is beneficial in that it reduces the HAZ in metals, produces deep penetrations, and can join dissimilar metals without creating cracking. It is simpler to join materials together by butt joining and eliminate thousands of rivets and adhesives. The substitution of rivets for LBW or FSW is one of the processes that can reduce corrosion, weight, and cost, to name a few of the advantages. Corrosion is reduced or eliminated via these welding processes because single components replace panels that traditionally overlap one another by riveting, which has a propensity to retain moisture and corrosive products, thereby ultimately causing failure. Additionally, the problems associated with rivets and their respective holes are eliminated. Joints generally contribute to a myriad of types of stresses also, and they increase production costs. However, it is also impossible to construct very large panels from the perspective of manufacturing costs and maintenance because it is impractical when changing parts. Therefore, the three typical joining processes to date have been the use of fasteners, bonding, and welding.

Similarly, FSW can be used to weld panels, and the advantages include weight savings, reduced drilling of holes, and faster joining (Fig. 12). The materials being joined do not reach their melting point temperature, which is important to maintain a certain level of strength in the alloys.^[32] As a result, the jet Eclipse 500 eliminated thousands of rivets and fasteners.^[13,28,32] The process involves a tool that is not a consumable to weld by the process of friction and heating locally. The tool rotates and imparts heat to the metal and produces a solid-state weld. The tool is generally in the shape of a solid cylindrical shape, like a pin or rod with a concave section on the cylindrical tool connecting to the workpiece to be joined, and the workpieces are joined by clamping and supported by a backing plate.

ENDURANCE AND INTEGRITY OF AIRCRAFT COMPONENTS

The Corrosion Prevention and Control Program is the typical reference point in the aircraft industry. Therefore, there has clearly been a lack of education in relation to corrosion and how to counteract this through specific design, not only in aircraft but in almost all designs.^[22]

Many aging United States Air Force aircraft have been found to exhibit several structural degradation aspects such as pitting, exfoliation, corrosion, stress corrosion cracking, fatigue, lack of bonding, and delamination.^[21] Due to failure to adequately describe the corrosion once found in a fixed wing or rotary wing aircraft, while still in the primary stages of design, the consequence has proved to be dire. Pitting and crevice corrosion are most common in 2000 and 7000 series aluminum alloys.^[16,29] Crevice corrosion cannot be seen when it occurs as it exists in the base of the crevice, and it cannot be seen as it is progressing,

Fig. 12 Schematic showing FSW: (a) commence welding; (b) force down to consolidate; (c) weld is advancing; and (d) completion of weld and withdrawal of tool

thus making it a lot more severe than pitting corrosion.^[16] Crevice corrosion has been found in certain aircraft in lap joints. The reason for this was speculated to be more likely due to moisture occurring as a result of condensation solution being trapped near the fastener heads, thus forming a galvanic couple. As a result, the grains were compromised via intergranular attack, further developing into exfoliation.^[19] This type of corrosion typically occurs in regions within grains that are not protected, such as in rivet holes or plate ends.^[15]

Energies that exist within grain boundaries are much higher than energies that exist within the grains, and for this reason, stresses are greatly increased when the load is applied normal to the grain boundaries, thus inducing stress corrosion cracking.^[1,3,17,29,33] High-strength aluminum alloys 2000 series and 7000 series^[27] exhibit grain boundaries that are elongated in the rolling direction, which makes them more susceptible to preferential corrosion. Since the 7000 series has copper and zinc among its principal elements, it is these very elements that gather at grain boundaries and leave certain sites free from precipitates. Aluminum is anodic in comparison with the copper in the galvanic series; hence, its reaction causes the grain boundaries to preferentially corrode, also known as intergranular attack. Generally, in the 2000 series, the 2024-T3 is used for skins, and in the 7000 series, 7075-T6 is used for stringers and frames.^[2] 2117-T4 is among the most widely used rivets in aircraft, but it is only used where there are lower strength requirements. The upper wings in subsonic aircraft utilize 2024-T4 because they are better in compression, whereas

the lower wings utilize 7075-T73 as they are better in tension.^[35] The 2000 series alloys are designed to be clad; otherwise, they will undergo intergranular corrosion. However, cladding effectively decreases the fatigue properties of mechanically fastened or riveted joints.

Crevice corrosion is one of the most common and sinister types of corrosion that exists, because it typically sets in the joints that overlap one another, particularly in the fuselage where moisture can sit in the crevice geometries for long periods, thus creating localized attack. Crevice corrosion does not only take place between metal joints only but may occur also between a metal and nonmetal. It is in lap joints, e.g., in the fuselage, where the oxygen potential is at its lowest and becomes a hidden form of corrosion (Fig. 13). Regions within metals have different electrochemical potentials to one another, and the energy may exist in the form of chemical and electrical potential energies. The base of the crevice is anodic and the mouth is cathodic, thus producing oxidation. The anodic reaction (oxidation) sections lose electrons, $M \rightarrow M^+ + e^-$, and the cathodic reaction (reduction) sections gain electrons, $2H^+ + 2e^- \rightarrow H_2$.

Basically, any surface on a metal that is not exposed to the atmosphere (oxygen) will be unable to build an oxide layer to protect itself against corrosion. When an oxygen-deprived region is formed such as a pit in a metal, and in the presence of stagnant or stationary water, for instance, the metal ions are released from the metal within this pit and travel away from the pit and into the surrounding droplet/film of water. The surface of the metal may dry out, or the cathodic or oxidation reaction on the metal surface takes place and protects

Fig. 13 Illustration of typical crevice corrosion: (a) aluminum sheets connected by bolt; (b) sheet connected by rivet

the metal due to excess oxygen present. These localized types of crevices are more menacing in nature than other types of corrosion such as uniform corrosion, because the sites are covered and not detected easily. The corrosion as a result can be extremely rapid because the metal ions from the cavity travel outward and react with the hydroxide ions forming corrosion (rust) at the mouth of the crevice. This action further prevents oxygen from migrating into the crevice/pit, thus enlarging the cathodic area to this anodic region, making corrosion much worse.

The famous Aloha Airline incident in 1988 illustrates the problem with crevice corrosion in the fuselage. The airliner was a 19-year-old Boeing 737 aircraft, and it was operated by Aloha. The airliner lost a major portion of the upper fuselage near the front of the plane in full flight at 7300 m altitude.^[34] The extent of damage is shown schematically in Fig. 14 and a photograph of the actual damage in Fig. 15. Several fatigue cracks also were found in the remaining aircraft, and in holes in the upper row of rivets of the lap joints in the fuselage.

Fatigue cracking would not have been an issue had the bonding remained intact. The adhesive cold bonding was the method for joining the skin panels, and fasteners or rivets were used along with this bonding technique in order that surface contact was achieved. This method allowed the bonding adhesive to transfer the loads between skin panels. Although the adhesive was breaking down, corrosion was setting into the joints and this resulted in the final debonding, thus causing the fasteners to carry the balance of the loading for which they originally were not intended for. The pressurization of the cabin was repeated, which meant that the cycles ultimately led to cracks forming at the fastener holes. The aircraft was continually subjected to pressurization on every flight as the cabin is pressurized after takeoff in order that passengers are able to breathe an atmosphere, which is similar to that close to sea level. The air actually gets thinner as the altitude is increased. The cabin is depressurized as the aircraft is reducing in altitude, and there is very high exposure of corrosion due to excessive saltwater in proximity at most times. Thus, all

Fig. 14 Schematic description of the Aloha aircraft incident

Fig. 15 Damage caused as a result of crevice corrosion in the fuselage of the Aloha Airlines Flight 737^[44]

Fig. 16 Three basic types of lap splices used for construction of aircraft fuselages

of the above resulted in multiple site-metal fatigue damage. The multiple site damage was a result of the forming and linking up of fatigue cracks formed in the vicinity of the rivet holes. However, lack of experienced inspectors maintaining the aircraft also did not help because the maintenance checks were inappropriate.

There are three basic types of aircraft fuselage lap splices, and these are shown in Fig. 16. A fuselage typically integrates two or three different types of splicing. Certain manufacturers either rivet or seal the lap joints, whereas other manufacturers rivet and use adhesive bonding.^[31] The main problem with the Aloha incident, as

mentioned previously, was that the panels in the fuselage that were overlapping one another would not have failed if the bonding had held them together firmly.^[45] Corrosion inside lap joints commonly referred to as crevice corrosion leads to a buildup of voluminous corrosion products inside the lap, resulting in a pillowing effect, which is highly undesirable and creates an extremely dangerous condition. The overlapping surfaces separate, as shown in Fig. 17. The corrosion product in the fuselage joints is referred to as aluminum oxide trihydrate and has an increased volume expansion relative to aluminum, as shown in Fig. 18. This buildup of voluminous corrosion products also creates an undesirable increase in stress levels near critical fastener holes. It is common for rivets to fracture due to high tensile stresses which result from pillowing.^[30] Studies have shown that an increase in volume of corrosion buildup in a joint also results in an increased level of stress, and this increase in stress level therefore is not only dependent upon the sectional thickness loss due to corrosion.^[30] This type of corrosion—pillowing in lap splices—is causing immeasurable damage in both commercial and military aircraft, and this is more so predominant in aging aircraft.

The aluminum oxide trihydrate is insoluble and tends to remain in position in the joints, hence forming the bulging or pillowing effect within the skins.^[5] Depending upon the location of pillowing, it was found that generally as pillowing increases, the stress intensity increases for the crack edge along the faying surface, resulting in rapid growth of faying surface cracks. In rivet regions on the outer surfaces, however, experiencing compressive stresses, as opposed to tensile stresses, there seems to be a reduced growth of faying surface cracks.^[5]

Because aircraft material generally require joining between one and another, it is often difficult to analyze precisely the stresses in riveted sections. However, assumptions, large safety factors, and experience combined yield overall safer designs. A lap joint indicating two plates connected via rivets or bolts is shown in Fig. 19. This is one of the simplest joints used in construction. The distance between each of the rivets along a row is known as the pitch, and the distance between the rows of rivets is known as back pitch, transverse pitch, or gauge.

A rule of thumb for applying the pitch distance in aluminum or steel plates is three times the diameter of the rivet or bolt, and the minimum edge pitch closest the rivet adjacent the edge is one and half times the rivet or bolt diameter. If the assumption is to apply edge loads, and that the rivets are of a particular diameter and are at a certain distance away from one another, and also that the distance from the location of the rivets is a certain distance from each of the plates, then there can be three possible types of failure modes: (1) rivet shear, (2) rivet/plate bearing failure, and (3) net section failure, and these will be described next.

Rivet shear: The rivet or bolt as shown in the side view of Fig. 20 is placed in shear. The calculation for the shear

Fig. 17 Pillowing of lap splices in aircraft

Fig. 18 Relative volume of aluminum corrosion products

stress is the force applied that is parallel to the area in shear and divided by the area.

The rivets or bolts may fail across their diameters as shown in Fig. 20 at the plate joint location, and the formula is represented as follows:

$$P_{\text{rivet shear}} = N \left(\frac{1}{4} \pi d^2 \right) \tau_{\text{all}}$$

where:

$P_{\text{rivet shear}}$ = Shear strength of the riveted or bolted system

N = Number of rivets or bolts in shear (in a lap joint with one cover plate)

$\pi = 3.1415$

d = Diameter of the rivet or bolt

τ_{all} = Allowable shear stress for rivet or bolt

Rivet/plate bearing failure: Either the rivet or plate material behind the rivet will fail in compression.

Fig. 21 shows an elevation view of the plates with a rivet holding them together. When the loads are applied to the plates, it can be seen in the plane view in the schematic

Fig. 19 Lap joint showing rivets or bolts penetrating through two plates and connecting them together

Fig. 20 Side view of lap joint showing forces applied parallel to the area in shear

Fig. 21 Illustration showing (a) section, (b) compression into sheet adjacent hole, and (c) compression being induced upon the rivet due to the top plate being pulled into the rivet

that the top plate is actually pulled into the rivet. The plate behind the rivet is therefore in compression. In either case, depending upon several factors including the compressive stress allowable for either the rivet or the plate, either the rivet or plate may fail in compression.

The areas of the plate and rivet being under compression and the vertical cross-sectional area of the rivet where the area of the plate contacts the rivet is placed in compression are shown in Fig. 22.

The area under shear stress multiplied by shear stress is considered to be the load that determines the cause of failure. Therefore, generally, the area in compression along with the vertical cross-sectional area of the rivet are considered to be the area of the rivet in compression and also the area of plate in compression.

$$P_{\text{bearing}} = N(d \cdot t) \sigma_{\text{All}}(c)$$

where:

P_{bearing} = Compressive strength of the riveted or bolted system or plate

N = Number of rivets or bolts in compression

d = Diameter of the rivet or bolt

t = Thickness of the plate

$\sigma_{\text{All}}(c)$ = Allowable compressive stress for the rivet or bolt or plate

Net section failure: The rivet row locations generally permit a failure of the plate when the plate is in tension; thus, tensile failure occurs first at the hole locations in the plate. If the plate material is cut at the first rivet row location, then the plate material is in tension. To determine the load, the plate can withstand before failure in tension occurs; the area that is placed under tension is multiplied by the allowable tensile load or stress. The area is typically the cross-sectional area of the plate. Because the plate is torn at the rivet locations, the diameter of the

Fig. 22 Region of compression in the regions of plate and rivet, typically considered to be the vertical cross section of the rivet

rivets must be deducted from the width of the plate, as the area of the plate is reduced by the rivet holes. Calculations for rows beyond the first row are a little more detailed and not intended for the scope of this article. However, the rows beyond row 1 actually carry less loading than the first row as some of the loading is transferred to the next plate:

$$P_{\text{1st Row}} = (w - d \cdot n) \sigma_{\text{All}}(t) t$$

where:

$P_{\text{1st Row}}$ = Tensile strength of plate at the first rivet row

w = Width of the plate

d = Diameter of the rivet

n = Number of rivets in a row

$\sigma_{\text{All}}(t)$ = Allowable tensile stress on the rivet or plate

t = Thickness of the plate

CONCLUSION

Fasteners for structural applications are not only dependent upon their own properties but are also very much dependent upon the structures to which the fasteners are connected. It is a holistic approach, when considering design for mechanical joints. All materials must be examined on a micro and a macro level, and design philosophies such as “damage-tolerance” and “fail-safe” are necessary to take into account with structures adjacent and in connection with any fasteners, bolts, or rivets. Fastener design alone is not enough, nor is it simple to design, because many factors must be taken into account to ensure longevity so that it is fit for purpose. Preloading of bolts is a requirement in design, but this also depends upon the stiffness of the metal or composite, and then there is the plating or coating on the fastener that must withstand certain temperatures; otherwise, hydrogen embrittlement and other issues contribute to the degradation of the fastener. Increase in temperature or skin friction effects in the aircraft creates drag whereby further design is required to control the level of drag and maintain material integrity. Galvanic corrosion is the largest problem only if dissimilar metals and or graphite fiber is in contact with aluminum material, but this can be eliminated by removing aluminum and substituting with titanium or placing a suitable protective glass barrier between the two materials. The replacement of rivets and fasteners for welding has been successful with the use of LBW and FSW as many of the mechanical properties are also improved, but also there are some disadvantages in these methods, and the benefits must be weighed against these nonbenefits in every situation. Because aluminum sheets are still commonly used in many aircraft, and they mostly comprise of riveting, some corrosion is almost inevitable in these structures and must be assessed on a regular basis, as the crevice or pitting type of corrosions do not give much notice and are not detected without effort.

From the literature reviewed, it was also evident that in order to gain a credible understanding of fasteners, bolts, and rivets, all of the materials in an aircraft that require joining would need to be assessed not only on a macroscopic level but also on a microscopic level. It would appear firsthand that the design for fasteners, bolts, and rivets for use in aerospace structures would not at all be difficult. Unfortunately, this is not the case, and as discussed throughout this article, these items require a more pragmatic and empirical approach to designing suitable connections for a diverse range of materials. That is, whether the material is a metal or a composite component or a combination of both requiring to be joined, these components need to be assessed in greater detail so that the final design is not dictated solely by the mechanical joint. The countless variables similar to those discussed throughout this article, although only limited, must all be taken into account. Incorrect designs and/or the absence of data and environmental factors, temperature, initial preload, fatigue, metal and composite galvanic corrosion, orientation of fibers, hidden corrosion in metals, and so on to choose the type of fastener required are essential for appropriate design.

Aircraft Structural Integrity: Corrosion Effects

Bruce Crawford, Chris Loader, and Timothy J. Harrison

Defence Science and Technology, 506 Lorimer St, Fishermans Bend, Victoria, 3207, Australia

Abstract

Corrosion damage can significantly reduce the structural integrity of aluminum alloy components in aircraft. This is a serious threat to the airworthiness of aircraft which means that corrosion prevention and repair are a major cost to aircraft operators. This article details a practical approach to the management of corrosion in aircraft by describing the forms of corrosion that are common in aircraft, the detection and measurement of these forms, and how they affect the airworthiness of aircraft designed using the dominant airworthiness philosophies. It concludes with a brief outline of how the structural integrity effects of each type are modeled.

Keywords: Aircraft structural integrity; Corrosion; Damage tolerance; Exfoliation; Fatigue; Intergranular corrosion; Pitting; Safe life; Stress corrosion cracking.

INTRODUCTION

High-strength aluminum alloys have been used in commercial, military, and general aviation aircraft since 1917. The high specific strength of aluminum alloys has facilitated the design of lightweight but strong and durable airframes. The ongoing need for lighter, stronger, and higher-performance aircraft has driven the development of new aluminum alloys and the continuous improvement of those that already exist.^[1]

Unfortunately, airframes degrade as they age. Fatigue is the most prevalent mechanism, but corrosion is also significant. In general, corrosion damage in aircraft is localized either due to defects in the passivating oxide film on aluminum alloy components or due to the failure of protective coatings such as anodizing, conversion coatings, primers, paints, and corrosion inhibiting compounds.^[2]

In some cases, localized corrosion has minimal effect on the airframe's static strength as the reduction in load carrying section of the airframe is minimal; in other industries, particularly the oil industry, corrosion can introduce hydrogen embrittlement in pipeline steel, leading to a reduction in toughness and ductility and increasing susceptibility to static failures.^[3] In aircraft, corrosion dramatically reduces fatigue endurance by promoting the initiation and growth of fatigue cracks. Undetected or unchecked corrosion damage can cause structural failures and the potential loss of aircraft. The loss of a trailing edge flap (TEF) from an RAAF F/A-18 in 1981^[4] and the inflight disintegration of a Boeing 737 due to severe exfoliation^[5] demonstrate this.

Corrosion management in aircraft is commonly viewed as an economic issue (with a number of studies attempting to determine the cost of corrosion in terms of gross national product^[6–9] and a US dollar amount,^[10–12] and not as a threat to safety-of-flight.^[13] However, a 1995 survey by Hoepfner attributed 633 aircraft incidents over 20 years, which destroyed 87 aircraft and killed 10 people, to corrosion or fretting.^[14]

Fleet operators typically remove corrosion on aircraft on a “find and fix” basis.^[15,16] Corrosion inspections are carried out during regular maintenance based on aircraft flying hours, and during additional inspections based on historically determined time intervals. Upon detection, corrosion is removed by buffing or grinding, and the location is then assessed against structural criteria. The component is repaired through reapplication of the protective paint scheme, if the material removed is within structural limits. Otherwise, the component is repaired or replaced. Finally, an attempt is made to identify the cause of the corrosion and means by which it or similar events can be prevented in future.

An alternative method to removing corrosion called “anticipate and manage” has been proposed^[15,16] and developed. This method allows the extent of damage caused by corrosion to be quantitatively assessed, and then repaired at a more convenient time, which usually results in cost savings. It also allows corrosion inspections to be optimized to prevent unnecessary maintenance actions. It has been used by the Royal Australian Air Force to manage the widespread exfoliation and pitting corrosion damage that has occurred to the trailing edge structure of the wings of its C-130J-30 aircraft,^[17] Fig. 1. In this case it was

neither economically nor operationally feasible to ground the entire fleet to repair the wings. Instead, the aircraft are being regularly inspected to ensure their airworthiness until each can be repaired during scheduled depot maintenance.

STRUCTURALLY SIGNIFICANT FORMS OF CORROSION

This section reviews the forms of corrosion that have a significant effect on aircraft structural integrity. These are:

1. Environmentally assisted cracking.
2. Pitting corrosion.
3. Crevice corrosion.
4. Galvanic Corrosion.

These forms of corrosion reduce aircraft structural integrity by one or more of the following mechanisms:

- i. Acting as a fatigue initiator by increasing local stresses.
- ii. Reducing the load carrying capacity of a component by decreasing its effective thickness.
- iii. Embrittlement of the material that accelerates fatigue crack growth and reduces fracture toughness.

The first two of these mechanisms persist even when there is no active corrosion underway as their effects are mechanical. In contrast, embrittlement can be either ongoing or transient. Note that these forms of corrosion do not occur in isolation. For example, pitting corrosion often precedes exfoliation, intergranular corrosion (IGC), and stress corrosion cracking (SCC) as it allows the corrosive

environment to penetrate the protective passivating oxide film of aluminum alloys.

Environmentally Assisted Cracking

Environmentally Assisted Cracking (EAC) encompasses corrosion fatigue, SCC, exfoliation corrosion, and IGC. All of these forms of corrosion involve the growth of cracks either along grain boundaries or through grains due to the presence of a corrosive environment and in the case of SCC, a stress.

Aluminum alloys with a high copper content, such as 2xxx-series aluminum alloys and some 7xxx-series alloys, are more prone to EAC than low copper alloys.^[18] This is because copper depleted regions, which generally occur at grain boundaries, are anodic compared to copper-rich regions and so are dissolved preferentially. Overaged alloys are more resistant to EAC than peak-aged alloys as overaging creates a more uniform distribution of copper-bearing precipitates.^[18] This improvement in corrosion resistance is why overaged alloys, despite their lower strengths, have replaced peak-aged alloys in modern aircraft.

Corrosion Fatigue

Corrosion fatigue is where fatigue crack growth is accelerated by a corrosive environment being present during fatigue loading. Several mechanisms for corrosion fatigue have been proposed but it is currently unclear which is dominant.^[19] Even the presence of water vapor can increase fatigue crack growth rates. Hydrogen embrittlement of the surrounding metal can be an additional factor present with corrosion fatigue, which can cause a loss of residual strength; however, this only occurs under limited circumstances.^[20] Corrosion fatigue caused the in-flight failure of the TEF lug of the RAAF F/A-18.^[4] The growth of the fatigue crack surrounding the corrosion pit, similar to that in Fig. 2, was accelerated by the humid salty air that the F/A-18 was flown in. When the crack reached a critical length, the lug failed and the TEF detached from the aircraft. Corrosion fatigue is less problematic for aircraft flying at high altitudes as the low temperatures and low humidity at these altitudes prevent corrosion fatigue.^[21]

Stress Corrosion Cracking

SCC is a form of crack growth in a susceptible material, induced by the simultaneous presence of a tensile stress and a corrosive environment. Removal of any of these three factors will prevent SCC.^[22] Previously, cases of SCC have been assessed using static loading to ensure safety,^[16] whereas the current approach uses a combination of material selection and the widespread application of corrosion inhibiting compounds. Typically, the easiest factor to remove, at least at the design stage of an aircraft, is the susceptible material. This is why overaged aluminum alloys have replaced

Fig. 2 Corrosion pit and corrosion fatigue crack on the fracture surface of a failed TEF lug from an RAAF F/A-18.^[4] Corrosion fatigue is indicated by the brittle appearance of the fracture surface

Source: © Commonwealth of Australia.

peak-aged alloys in aircraft designed after 1970, despite their lower mechanical strength. For example, the C-130-H had extensive amounts of 7075-T6 in its airframe which was largely replaced with 7075-T73 in the C-130J-30 model, while the Hawk Mk. 127 fighter trainer and F/A-18 use the

overaged alloys 7010-T7651 and 7050-T7451, respectively, as their principal structural alloys.

IGC and Exfoliation Corrosion

Exfoliation and IGC are caused by preferential corrosion of grain boundaries in susceptible materials. IGC and exfoliation both initiate from corrosion pits, especially those in the bore of fastener holes where end grains are exposed. Figure 3 shows lamellar IGC in 7075-T6 wing-skin from an RAAF AP-3C^[23] and the growth of fatigue cracks in the vicinity of this form of corrosion. The IGC is lamellar due to the pancaked microstructure of the alloy. However, this form of IGC is atypical. IGC more typically grows along multiple grain boundaries, branching and feathering. Figure 3a also shows exfoliation at the bottom right of the component, where it was in contact with jet fuel. The IGC and exfoliation in this figure initiated at a fastener hole, which is the uneven edge at the figure's right. Recent research has shown that IGC can have a detrimental effect on structural integrity due to the presence of the corrosion pit and possible corroded inclusions along the IGC fissure (that act as a void) with depths of only 1 mm.^[24]

Figure 1 shows an example of severe exfoliation in a component of AA7075-T6. Note the swelling of the component. Exfoliation is IGC that occurs near a component's

Fig. 3 (a) Composite micrograph showing IGC from a fastener hole in the wing skin of an RAAF P-3.^[23] There is also exfoliation present at the skin bottom surface, which was exposed to jet fuel. (b) Fatigue fracture surface from IGC at a fastener hole showing the interaction of the fatigue crack (yellow lines show successive crack fronts) with the IGC fissure

surface, which is indicated in Fig. 1 by an arrow. Wedging stresses induced by corrosion product trapped in the metal's grain boundaries cause its outer layers to spall. This reduces the thickness of the component that can bear a load, which reduces its apparent yield strength by increasing its mean stress.^[16,25–27] However, Pantelakis and Kermanidis showed that exfoliation reduced the ductility of aluminum alloys 2024-T351 and 6061-T6 and that this reduction persisted even when the corroded material was machined away. Pantelakis and Kermanidis attributed this to hydrogen embrittlement and showed that heat treatment restored the alloys' ductility.^[28]

Exfoliation greatly reduces fatigue life. Figure 4a from Ref. [25] shows this for coupons of 2024-T3 and 7075-T6 exposed to exfoliation corrosion (EXCO) solution, which is a severely corrosive liquid.^[29] Both alloys exhibit a rapid initial decrease in fatigue life for exposure periods up to 25 hours followed by a plateau to exposure times of 300 hours. Burns et al. reported very similar results for

7075-T76511 corroded using a variety of solutions of different severities.^[30]

Pitting Corrosion

Pitting is a localized form of corrosion where small volumes of a metallic body are oxidized in an electrolyte to form a void. Pitting occurs in aluminum alloys as they have a passivating layer on their surface, which, under certain conditions, can perforate in small areas to form pits. In aluminum alloys, these conditions include the presence of chloride ions in aqueous solutions, and second-phase particles which provide a galvanic driving force for corrosion. Once perforated, the passive film may not reform due to the creation of a localized environment within the pit. This leads to stable growth of the pit. See^[31] for an overview of the electrochemistry of pitting. Figure 2 shows corrosion pits surrounded by a corrosion fatigue crack in an AA7050-T7451 TEF lug from an RAAF F/A-18.^[4]

Fig. 4 (a) Reduction in fatigue life of 2024-T3 and 7075-T6 as a function of EXCO exposure time. (b) Schematic representation of the DST process zone model vs. approximate EXCO exposure times

Source: Reproduced from Sharp et al.;^[25] © Commonwealth of Australia.

Another RAAF F/A-18 lost a TEF in flight due to a similar pit in its TEF lug.^[4]

Pitting is recognized as an event-driven effect in aircraft^[31] that occurs over the space of hours, while fatigue typically occurs over many years. This means that except in the case of corrosion fatigue, fatigue is treated as having initiated from existing corrosion for aircraft structural integrity. This decoupling of corrosion and fatigue means that fatigue and corrosion can often be modeled separately. This is also the case for most intergranular and exfoliation corrosion where the formation of the corrosion can be modeled separately to its effect on aircraft structural integrity.

Corrosion pits reduce the fatigue life of aluminum alloys^[32,33] and components^[4] by acting as stress concentrators, which promote fatigue crack initiation. The stress concentration factor (K_t) of a hemispherical pit in uniaxial tension is around two.^[34,35] Corrosion pits in aluminum alloys typically have convoluted shapes^[4,32,36–39] so they will have K_t values exceeding two. Figure 5 plots constant amplitude fatigue life data for the alloy AA7010-T7651.^[32] It shows a reduction in fatigue life for the corroded condition of zero at 500 MPa to 90% at 270 MPa as well as a decreased fatigue limit compared to un-corroded material. Shekhter et al. found reductions in fatigue life of 16% at two load levels for high- K_t specimens of 7075-T6 ($K_t \approx 5$) tested using a fighter aircraft loading standard for fatigue evaluation spectrum.^[33]

Crevice Corrosion

Crevice corrosion is similar to pitting as it is localized and needs a concentration cell to continue growing. It occurs where geometric features, such as lap joints and fasteners, create occluded regions where electrolyte stagnates. The metal surfaces within the joint are anodic compared to its outer surfaces due to the lower concentration of dissolved oxygen within the occluded region leading to corrosion. The corrosion product has a higher specific volume than the parent aluminum, which forces the layers of the joint apart, except where the fasteners prevent this. This pillowing creates elastic stresses in the joint, which promote fatigue and SCC by increasing the mean stress.^[40]

Galvanic Corrosion

Galvanic corrosion occurs between dissimilar metals in direct electrical contact in the presence of an electrolyte. It occurs in aircraft when protective layers between metallic components break down or are absent, manifesting as corrosion at the interface between the dissimilar metals. Galvanic corrosion is common around joints between different metals, joints between metals and composites and around metallic fasteners as these are commonly made of different materials to the components being joined.

Figure 1 shows a trailing edge arrowhead from a RAAF C-130J-30 that has suffered severe exfoliation and

Fig. 5 Comparison of fatigue lives at a load ratio of 0.1 of corroded and uncorroded coupons of 7010-T7651 from Crawford et al.^[32] supplemented by additional data collected subsequently by the authors.^[60] Also shown are the lines of best fit made according to the method in DEFSTAN 00-970 and the Safe-SN curves calculated using the method in the same standard^[50]
Source: © Commonwealth of Australia, unpublished.

pitting damage due to galvanic corrosion. The trailing edge wing panels of this aircraft are composed of carbon epoxy composite. These panels are in direct contact with numerous aluminum alloy and steel components in the wing. The insulating layer between these components failed which allowed electrical contact between the skin panels and the underlying structure. The corrosion is driven by the graphite panel being more cathodic than the metal components.

FINDING AND MEASURING CORROSION DAMAGE

In contrast to fatigue cracks, corrosion can be relatively easy to find. Often it is the corrosion debris that is first detected, for example, the corrosion product around pitting corrosion or weeping from a fastener hole, rather than the actual corrosion itself. Additionally, corrosion damage is often widespread. In contrast, fatigue damage is typically restricted to critical regions. However, corrosion can also occur in hidden locations such as within joints or internal bays and locations not covered by regular maintenance. IGC and SCC can also be hard to detect unless the area is subject to ultrasonic inspection as they occur in the bulk of a material and their only visible manifestation may be some apparently minor pitting.

However, it is insufficient to just detect corrosion. To assess its effect on structural integrity, its severity must also be determined. In general, this is related to its size, which can be difficult to measure using nondestructive inspection methods such as visual and optical methods, radiography, eddy current methods, ultrasound, liquid penetrant testing, magnetic particle testing, acoustic emission, and thermography.^[41] The use of various types of NDI for different forms of corrosion raises the issues of how the size of corrosion damage should be defined for a given form of corrosion, component geometry, and NDI method. This is called a “corrosion metric”.^[15,42] Some commonly used metrics are described below.

Pitting and Crevice Corrosion

Pitting corrosion is generally removed upon detection, which is often as a result of a visual inspection, as it is a relatively easy repair. However, pitting corrosion can remain undetected when it is hidden from view. Finding hidden corrosion is far more difficult as common NDI methods are not well suited to finding the small, localized surface defects such as pits.

Research has shown that the effect of pitting corrosion on the structural integrity of aluminum alloy alloys is best estimated using either pit depth^[36] or area,^[32] Fig. 6a. Unfortunately, pit area cannot be measured in service. It is therefore necessary to use pit depth instead. The only practical way to measure pit depth in aluminum

alloys in aircraft structures is optically. The presence of corrosion product in corrosion pits in aluminum alloys, which obscures their base, means that even this measurement is inaccurate. Attempts have been made to use other metrics. Tugel investigated the use of surface roughness and mass loss as metrics for the effect of pitting.^[43] He found that fatigue life decreased as both metrics increased, but that there was severe scatter in these relationships.

Environmentally Assisted Corrosion

As stated above, EAC encompasses corrosion fatigue, SCC, IGC, and exfoliation. The current best practice in the RAAF for detecting and measuring IGC and SCC, specifically on the AP-3C, is ultrasonic thickness measurement if the plane of the EAC is parallel to the exposed surface, or Eddy Current inspection if the plane of the EAC is perpendicular and breaks the surface of the component. It can be used close to fastener holes, and the instruments are mobile enough to be used within the aircraft’s wing tanks. Measuring the actual length of EAC, however, is limited by this technique’s resolution, which has a detection limit of about 1–2 mm. Furthermore, ultrasonic scans can only detect a single layer of IGC, as the IGC fissure will reflect the great majority of the ultrasonic signal back to the probe. Where there are multiple layers of IGC, such as in Fig. 3a, only the layer nearest the surface where the probe is placed will be detected.

Exfoliation corrosion can be detected by visual inspection or search peening.^[44,45] The latter method is a process where the surface of a component is peened to reveal exfoliation corrosion damage. The exfoliation corrosion is revealed as the surface material overlaying it deforms far more than the surface of uncorroded material.^[44] Alternatively, if the back surface of the component is accessible, the depth and extent of exfoliation can be measured using time of flight measurements made using ultrasound.

INTERACTION WITH AIRCRAFT STRUCTURAL INTEGRITY PHILOSOPHY

There are three principal philosophies for managing the structural integrity of aircraft. These are the Safe Life, Damage Tolerance, and Fail Safe philosophies. This section will examine how corrosion affects aircraft designed using each of these philosophies. Useful summaries of these philosophies may be found in Akdeniz,^[46] Barter et al.,^[47] Hoffman and Hoffman,^[15] and Miedler.^[13] Mills et al. contains a useful discussion of the interaction between corrosion and structural integrity philosophy.^[48] Mills et al. propose a philosophy called “Holistic Structural Integrity Program” (HOLSIP), which explicitly considers the effects of corrosion, crack initiation, short crack growth, and other degradation modes.

Fig. 6 (a) Corrosion metrics for corrosion pits. (b) Illustration of principle of EIFS method

Safe Life Philosophy

The Safe Life philosophy was the first attempt to account for fatigue damage in designing and operating aircraft. Prior to its introduction, aircraft were designed purely on the basis of static strength. The loss of two de Havilland Comet aircraft in 1954 and five USAF B-47 aircraft in 1958 showed, however, that static strength could not assure safety in the face of fatigue.^[13,47] These incidents led to the development of the Safe Life philosophy. The fatigue testing of 221 ex-service Mustang wings by the Aeronautical Research Laboratory in the 1950s produced the data upon which the scatter factors used in the Safe Life philosophy are based.^[49]

The Safe Life philosophy assumes that a principal structural element contains no fatigue cracks or crack-like features when it enters service. It is therefore an attempt to predict when fatigue cracks initiate.^[15] The fatigue life of a primary structural element is estimated based on either analysis or from using fatigue test results. These fatigue

test results can include material, component, and sub-structure tests as well as full-scale fatigue tests. Scatter factors, which are based on service experience and testing encapsulated within standards, are then applied to these estimated or measured fatigue lives to determine a safe life. When the Safe Life philosophy is strictly applied, components are removed from service upon reaching their safe life. Nowadays, however, this is often uneconomic and Safe Life aircraft are transitioned to a “Safety by Inspection” basis to keep them in service.^[15]

Corrosion in an airframe invalidates the assumption of no cracks or crack like features. As an example, Fig. 5 shows the stress-based fatigue life results for the aluminum alloy 7010-T7651 from Crawford et al.^[32] These data have been analyzed using the “Safe-SN” method described in Defence Standard 00-970.^[50] In the Safe-SN method the fatigue lives are divided by a factor of 2.8 at high stresses and the stresses are divided by a factor of 1.49 where the fatigue life curve approaches the fatigue limit. The Safe-SN curve appears to provide a significant buffer

against variation in the uncorroded fatigue life (except at low stresses due to the increased scatter in the fatigue life). However, Fig. 5 shows that the corroded material has a shorter fatigue life than the Safe SN curve at all stresses and that the corroded material's fatigue strength at 10^7 cycles ($\sigma_{\infty} \cong 135$ MPa) is approximately 15% less than that of the Safe-SN curve ($\sigma_{\infty} \cong 160$ MPa). A Safe-SN analysis of the corroded material's data gives a σ_{∞} value of 90 MPa. Therefore, in this example, the Safe Life philosophy cannot accommodate the deleterious effects of corrosion on fatigue endurance.

Fail-Safe Philosophy

The Fail-Safe philosophy is based on the principle of having redundant structure in an airframe to ensure safety. This redundant structure is designed to bear the additional loads that result from structural failures until repairs can be made. Fail safe designs were widely used in commercial jet aircraft in the 1950s and 1960s. They were supplanted in the 1970s by damage tolerant designs as unexpected failure modes in aging aircraft became prominent.^[51]

The presence of corrosion undermines the fundamental tenet of the Fail-Safe philosophy as redundant structure is just as likely to suffer corrosion damage. The explosive decompression of Aloha Airlines Flight 243 on April 28, 1988 shows this. At the time of the accident, the aircraft had conducted 89,680 landings and flown 35,496 airframe hours.^[52] The bonding of the fuselage skin joints and tear straps failed, allowing humid, salty air to penetrate the airframe and corrode the tear straps in the fuselage, rendering them ineffective. The failure of the fuselage was caused by multiple fatigue cracks propagating along the rivets and linking up.

As the tear straps had also failed, the decompression of the fuselage was not controlled; instead, an explosive decompression occurred. Fortunately, the aircraft did not disintegrate, and the pilots were able to land the aircraft with the loss of only one crewmember.

Damage Tolerance Philosophy

In 1969, an F-111 aircraft lost a wing in flight after 104.6 flight hours due to a manufacturing defect.^[53] This grounded what was then a new aircraft fleet until its airworthiness could be assured. The US Air Force responded by developing the Damage Tolerance philosophy, which assumes the presence of fatigue cracks at critical locations in an aircraft's structure at the beginning of its life.^[13] For example, both corners of "fracture critical" holes are assumed to have a 1.27 mm corner crack on one corner of the hole and a 0.13–0.26 mm crack on the opposite side of the hole. These cracks are oriented perpendicular to the maximum principal stress, and their growth is modeled using fracture mechanics. The assumed sizes used far exceed the maximum pit sizes reported in the literature for aluminum

alloys both on and off aircraft. Therefore, fatigue cracks initiated by isolated corrosion pits are unlikely to threaten the damage tolerance of aircraft components at locations that are periodically inspected.

However, as pointed out by Mills et al.,^[48] locations in an airframe that are not considered fracture critical, which is the majority of the airframe, are subject to far smaller required initial defect sizes (e.g., 0.127 mm for a corner crack at a hole) as they must survive the aircraft's design lifetime without inspection. However, the growth of fatigue cracks from these locations is, in general, not explicitly modeled. The assumed crack sizes for both fracture critical and non-fracture critical locations are well within the size range of corrosion pits seen in service. It is also within the expected size ranges of clustered corrosion pits, IGC, exfoliation, and SCC. As a consequence, corrosion damage can undermine the airworthiness of damage-tolerant aircraft.

Holistic Structural Integrity Philosophy

The HOLSIP philosophy, which has been proposed by a consortium of US and Canadian researchers, extends the USAF Aircraft Structural Integrity Program. Its intention is to include, using physically realistic models, all relevant degradation modes in estimates of fatigue life and structural integrity to obtain more accurate estimates. This is in contrast to the other philosophies described above which use approximations, such as the equivalent initial flaw size (EIFS) method,^[54] to make estimates of remaining life. Examples of applications of HOLSIP are found in Refs. [55,56], while Ref. [48] explains its underlying rationale.

PREDICTING THE FATIGUE DEGRADATION OF AIRCRAFT

Before describing how corrosion damage may be incorporated into the fatigue life of aircraft, it is necessary to briefly describe how fatigue in aircraft is modeled and the sources of scatter inherent in fatigue. A detailed description of these models can be found in Hu et al.,^[57] who also describe the software tools developed to implement these methods.^[57–59] It is important to note that in assessing how the fatigue models described below can be adapted to incorporate corrosion, that decoupling of corrosion and fatigue is maintained. That is, that overwhelmingly in aircraft structural integrity, the concern is fatigue initiating from corrosion, such that fatigue models are required to incorporate prior corrosion rather than corrosion fatigue.

Predictive Models of Fatigue

The fatigue of materials and structures is generally modeled using either the fatigue life approach, which is the basis of the Safe Life philosophy, or the fatigue crack growth approach upon which the Damage Tolerance philosophy

is based. The fatigue life approach can be further subdivided into stress life, which requires testing of representative fatigue specimens, and strain-life methods, for which only smooth specimen data are needed. Figure 5 shows fatigue life data collected using the stress-life method.^[32,60] Strain-life methods are best suited to components under low-cycle fatigue conditions where cyclic plastic strain predominates, while stress-life methods are more commonly used for high-cycle fatigue conditions where plastic strains are absent. Strain-life methods are used in aircraft that experience high flight loads such as the F/A-18.^[15]

A major advantage of strain-life over stress-life is it only needs fatigue life data from smooth specimens tested using fully reversed loading. In contrast, stress-life requires data from specimens of various stress concentration factors and load spectra. Strain-life methods are also better able to predict fatigue lives for specimens or components tested under variable amplitude conditions.^[57] However, attempts to model the effect of corrosion using a fatigue life approach have been rare.^[15] As an example, the US Navy has developed an “equivalent stress riser” method based on notch factors to predict the fatigue life of AF1410 high-strength steel components on its F/A-18 aircraft.^[61]

In contrast to the fatigue life method, the fatigue crack growth approach is based upon fracture mechanics. In particular, the stress intensity factor range, ΔK is used as a correlating parameter for fatigue crack growth rates, da/dN , as suggested by Paris et al. in 1961,^[62] using the following equation:

$$\frac{da}{dN} = C \cdot \Delta K^n.$$

Numerous modifications have been proposed to the above equation to account for mean stress effects (Forman equation), crack closure (Elber strip yield, which is a modification to the Paris Law), fatigue thresholds (NASGRO), and fast fracture. The modification of ΔK to account for crack closure is ΔK_{eff} , the effective stress intensity factor range.^[59] Crack closure was first reported by Elber in the 1960s.^[63] Some of these crack growth rate models, taken from Ref. [64], are shown below:

Forman equation:

$$\frac{da}{dN} = \frac{C \cdot \Delta K^m}{(1-R)K_C - \Delta K}$$

Elber strip yield equation:

$$\frac{da}{dN} = C \cdot (\Delta K_{\text{eff}})^m$$

NASGRO equation:

$$\frac{da}{dN} = C \left[\left(\frac{1-f}{1-R} \right) \Delta K \right]^n \left(\frac{1 - \Delta K_{\text{th}} / \Delta K}{1 - \Delta K_{\text{max}} / \Delta K} \right)^p$$

In the above equations, C , m , n , p , and q are parameters used to fit these equations to experimental fatigue crack growth data, R is the load ratio, ΔK is the stress intensity factor range, ΔK_{max} is the maximum stress intensity factor, ΔK_{eff} is the effective stress intensity factor range, and ΔK_{th} is the threshold stress intensity factor.

The modifications described above can be used to model fatigue crack growth for constant amplitude loading. Numerous methods have been used to attempt to model variable amplitude loading, which is typically seen in aircraft (as opposed to constant amplitude loading). These methods include the equivalent stress approach (for short, repetitive load sequences) or cycle-by-cycle approaches, such as rainflow counting,^[65] where the crack growth is incrementally determined for each load cycle, thus effectively treating the variable amplitude loading as a series of constant amplitude loads. This gives a numerical integration to the following equation:

$$N_f = \int_{a_0}^{a_f} \frac{da}{F(\Delta K)},$$

where N_f is the overall fatigue life, a_0 and a_f are the initial and final crack sizes, respectively, and $F(\Delta K)$ is the crack growth model being used. To effectively model variable amplitude loading, these approaches also need to account for load history effects by utilizing (and recalculating at each iteration) ΔK_{eff} rather than just ΔK .

In some cases, the fatigue life and fatigue crack growth approaches have been combined to create a hybrid approach, where fatigue crack initiation is modeled using a fatigue life approach. Once initiated, the fatigue cracks are modeled using the fatigue crack growth approach. This hybrid approach was used by the RAAF, US Navy, Royal Netherlands Navy, and the Canadian Forces to transition the structural integrity management of the P-3C from its original Safe-Life design to Safety by Inspection.^[66]

Scatter in Fatigue Behavior

The initiation and growth of fatigue cracks in materials, components, and built-up structures are subject to scatter. This scatter arises from, amongst other factors, variations in microstructure, surface finish, applied loading, component dimensions, and stresses induced by manufacturing and assembly. These factors lead to significant scatter in the initiation and growth of fatigue cracks. Figure 5 illustrates the scatter that is typically seen in fatigue life data, and how it increases as the applied stress decreases. This behavior is commonly attributed to an increase in the difficulty of fatigue crack initiation as the cyclic stress decreases.^[67]

There is also scatter in fatigue crack growth rates. The definitive example of this can be found in a 1979 paper by Virkler et al. who conducted 68 nominally identical

fatigue crack growth tests on 2.54 mm thick specimens of AA2024-T3.^[68] All of Virkler's specimens were machined from a single lot of material. Analysis of Virkler's data indicate there is less than one order of magnitude of variation in fatigue crack growth rates. Schijve compared this variation with the literature for scatter in fatigue life and suggested that crack initiation causes far more scatter in fatigue life than crack growth.^[67]

There are additional causes of scatter in fatigue behavior that occur only in components and structures.^[67] These include

1. An increased variation in material behavior due to the use of materials from multiple lots.
2. The ongoing production of components over the course of years, which leads to differences in source materials, surface quality, and manufacturing processes.
3. Environmental factors such as the climate of the location where aircraft are stationed, i.e., stationing aircraft at humid versus arid airbases, and the resultant differences in corrosion^[69] and fatigue crack growth rates.^[21,70]
4. Errors in manufacturing and uncertainties in the flight loading of aircraft.

Schijve states that these factors outweigh the scatter due to materials described above.^[67]

The Equivalent Initial Flaw Size Method

A commonly used method of modeling corrosion damage in aircraft components is to represent the damage as a fatigue crack with equal fatigue life and, ideally, fatigue crack growth behavior. This method is called the EIFS method, and its basis is illustrated in Fig. 6b. Rudd and Gray developed the EIFS method to model the effect of hole quality on the fatigue life of the F-4B/C/D Phantom and A-7 Corsair II.^[54]

The EIFS method has since been used to predict the growth of fatigue cracks from numerous types of damage and discontinuities in airframes, aircraft engines, engineered structures, and materials. Figure 6b shows two crack length curves as a function of time. One curve (black) is the actual growth of a fatigue crack from a corrosion pit. The other curve (red) is the growth of the equivalent crack from an artificial initial size, i.e., the EIFS. The EIFS value is selected so that these two curves correspond as much as possible. Various methods have been used to do this. These include quantitative fractography and computational methods using software such as AFGROW^[58] or FASTRAN^[59] to determine the optimal EIFS value.

The EIFS method deliberately avoids modeling crack initiation and short crack growth. It instead assumes that the fatigue is entirely due to long fatigue crack growth. Therefore, EIFS values are not related to the size of any

microstructural feature. Instead they are a product of the model used to derive them and so cannot be used with a different model. Therefore, an EIFS distribution cannot be used with a material, component, loading, or fatigue crack growth dataset other than that used to derive it. This is because it convolves the uncertainty in each of these factors.^[71]

PREDICTING HOW CORROSION AFFECTS AIRCRAFT STRUCTURAL INTEGRITY

At the time of writing, there is no one model that can be applied to every type of corrosion. This is due to the complex and distinct stress-concentrating features associated with each type of corrosion.

Pitting and Crevice Corrosion

The effect of pitting corrosion on the structural integrity of aluminum alloys has received a great deal of attention starting in the 1920s.^[72] Harmsworth^[73] treated corrosion pits as notches to model the effect of pitting on fatigue life. Since the introduction of damage tolerance, however, pitting has mostly been modeled using the EIFS method.^[32,33,35,74–77]

The EIFS approach models pits as cracks using fracture mechanics. In most cases, the distribution of EIFS values is unrelated to the pit size distribution. Sometimes the EIFS has been linked to a corrosion metric, such as by Crawford et al.,^[32,77] who used pit area as the corrosion metric and fatigue crack growth data derived from the same material and specimen geometry as the corroded fatigue life specimens. The distributions of the EIFS and pit size were very similar (the mean EIFS was 8% larger than the mean pit size) but there was no one-to-one correlation between pit size and the EIFS for any of the 300 specimens tested. Despite this, Crawford et al.^[77] were able to accurately predict the proportion of failures due to pitting and the fatigue lives for corroded and uncorroded low- K_t specimens with offset corrosion locations.

Other researchers have moved beyond the EIFS method to approaches which attempt to realistically model the development of fatigue cracks from corrosion pits. For example, Jones and Hoepfner investigated the development of fatigue cracks from preexisting corrosion pits and the effect of these pits and local microstructure on short crack growth in 2024-T3^[78] and 7075-T6.^[79] Similar work has been undertaken by Arunachalam and Fawaz^[80] and Burns et al.^[35]

Environmentally Assisted Cracking

Corrosion Fatigue

Given that corrosion fatigue is fatigue crack growth accelerated by a corrosive environment, any attempt to predict it

requires fatigue crack growth rate data that were collected in the same environment. Failure to do so produces non-conservative fatigue life predictions. Corrosion fatigue is also strongly affected by the loading rate, so loading rate data are also needed to make the best possible predictions of fatigue crack growth.^[67]

Stress Corrosion Cracking

Predicting the initiation and growth of SCC in aircraft has been unsuccessful to date. In general, SCC is better managed by using more resistant alloys or heat treatments, corrosion protection coatings, and corrosion inhibiting compounds. This is because of the variability in the factors that control the growth of SCC and the difficulty of quantifying these factors. In particular, the stresses that induce SCC are difficult to measure or estimate.

Intergranular Corrosion

Very little research has been conducted for predicting how IGC affects the fatigue behavior of aluminum alloys.^[24,81–83] Harrison et al. recently developed a model for the effect of IGC on structural integrity. This model examined the effect of the IGC around fastener holes, shown in Fig. 3a on the structural integrity of the RAAF AP-3C, finding that the effect was mostly due to the pitting corrosion from which the IGC initiated. Corroded inclusions along the IGC fissure (caused during the corrosion process) have a comparatively minor effect on fatigue life, and this effect decreased as inclusions became more distant from the hole. Repairing this pitting corrosion, by refinishing the hole, is a possible method of removing the effect of the IGC on fatigue life.

Exfoliation Corrosion

Several models have been developed to predict how exfoliation corrosion affects fatigue life.^[25,84,85] The first of these was the process zone model, which models exfoliation corrosion as a notch with a sharp crack at its base, Fig. 4b.^[25] The notch represents a corrosion pit while the sharp crack represents an intergranular fissure emanating from the pit. As the exfoliation grows, the loss of cross-sectional area caused by exfoliation is simulated by reducing the cross section of the material, which increases the average stress. This model gave accurate predictions of fatigue life using FASTRAN II^[59] for artificially corroded specimens, but could not be used in service as the size of the intergranular fissures cannot be measured on operational aircraft. It was subsequently modified by Mills who used the size distribution of the constituent particles in the alloys being modeled as the size of the sharp cracks.^[84] Three-dimensional finite element modeling of the corrosion pits produced estimated lives 8% above the actual lives. Together these models demonstrated that modeling exfoliation corrosion as just a

thinning of the material grossly underestimated its impact on fatigue life and structural integrity.

The process zone model was then used by the National Research Council of Canada (NRC) of Canada to predict the fatigue lives of naturally exfoliated specimens machined from material extracted from an ex-service aircraft.^[86] They found that the process zone model was nonconservative by a factor of 2 in its fatigue life predictions. This was attributed to differences between the natural exfoliation of the NRC specimens and the artificial exfoliation of the Defence Science and Technology Group (DST) specimens.

The limitations of the process zone model prompted the NRC to develop a new model for exfoliation corrosion called the Soft Inclusion model where the exfoliated region of the specimen is represented in an FE model of the specimen by an isotropic inclusion of reduced modulus.^[84] The reduced modulus accounts for the decreased stiffness of the exfoliated region due to lost material.

CONCLUSION

The article has provided an overview of how corrosion, in its various forms, damages the structural integrity of aircraft and the operational and economic costs of this damage. The examples in this article have come from military aircraft but the mechanisms and models of degradation and failure described here are equally applicable to civil and general aviation aircraft.

This article has also shown how corrosion damage invalidates the assumptions of the various philosophies used to manage the structural integrity of aircraft. Finally, the models that have been developed to predict the effects of these various forms of corrosion were discussed.

ACKNOWLEDGMENTS

The authors would like to thank their colleagues at the Defence Science and Technology Group for providing the examples of corrosion damage and its interaction with fatigue that have been described in this article. They also acknowledge Dr. Richard Chester of DST Group and Mr. Anthony Grant of Asia Pacific Airbus Group for their reviews on the article.

Al-Mg-Si: Microstructural Analysis

Marcello Cabibbo

DIISM, Università Politecnica delle Marche, Via Brecce Bianche, Ancona, 60131, Italy

Abstract

This article presents two case studies referring to the severe plastic deformation applied to Al-Mg-Si alloys. In a first case study, an Al-Mg-Si alloy in a T6 temper is subjected to equal-channel angular pressing (ECAP), and all the microstructure strengthening contributions to the alloy yield stress are determined through specific modeling and then validated. In a second case study, two Al-Mg-Si alloys, one with Zr addition and a second with Sc-Zr addition, are subjected to ECAP after a T6 temper in an overaged status. In the second case, the role of the Zr- and Sc-Zr-containing nanometer dispersoids is described, and the related strengthening effect is modeled according to the models presented in the first case study.

Keywords: Al-Mg-Si alloy series; Strengthening mechanisms; Secondary phase particles; Role of Sc and Zr; Role of SPD; ECAP.

INTRODUCTION

The Al-Mg-Si series alloys are recognized as some of the most important aluminum alloys for the production of mechanically resistant sheets, plates, extruded components, and for drawing and, sometimes, deep drawing processes. The automotive industry, the transport industry, and the civil engineering, especially as aluminum extruded window frames, are worldwide recognized fields of applications for the Al-Mg-Si alloys.

The mechanical properties of this class of aluminum alloys are guaranteed and tailored by the heat treatments and different industrial meaningful tempers (T4, T5, T6, and T8). The tempered alloys undergo specific and well-established secondary phase precipitation sequences that are chiefly responsible for the alloy microstructure strengthening processes. The precipitation sequence of the Al-Mg-Si alloy series can be also modified to some extent, by the addition of other strengthening meaningful elements, of which two of the most effective are Cu and Ag.

In addition, further alloy strengthening can be induced by applying a pre-strain to the tempering treatments. In this sense, the severe plastic deformation (SPD) processes are able to strongly improve the alloy yield stress through the combined effect of a large fraction of newly introduced dislocations, by the SPD, and the precipitation sequence induced by the temper treatment.

This article is intended to describe the role of SPD techniques on the precipitation sequence and the related strengthening effect of Al-Mg-Si alloys, and Al-Mg-Si alloys containing grain refiners elements, such as Zr

and Sc. Two case studies are presented here, and both describe the strengthening mechanisms of Al-Mg-Si alloys subjected to ECAP.

In a first case study, the alloy is SPD in a T6 temper at its hardness peak, and the role of the newly introduced dislocations, and the cell and grain boundary modifications, induced by ECAP, in the strengthening secondary phase particles is addressed. To do this, all the strengthening factors, and a specific strengthening contribution superimposition, are modeled. The model is validated through transmission electron microscopy (TEM) analyses and data acquisition.

In a second case study, the effect of grain boundary pinning dispersoids on Al-Mg-Si alloys, subjected to ECAP, is addressed. Two alloys, namely, Al-Mg-Si-Zr and Al-Mg-Si-Sc-Zr, were taken into consideration. Both alloys are subjected to ECAP at the same experimental conditions followed for the first case study. The same strengthening model, described in the first case study, is applied and validated through TEM inspections.

The two case studies presented here are intended to give a sufficient and sound demonstration of the quite important role of SPD techniques applied to the Al-Mg-Si series alloys to optimize the alloy strength due to the peak aging T6 temper. The two cases are representative of conventional Al-Mg-Si alloys (first case study) and dispersoids-grain refined alloys (second case study).

The first part of this article gives a background on the technological impacts, age-hardening secondary phase precipitation sequence, and role and importance of the SPD techniques applied to Al-Mg-Si alloy series.

Technological Impacts of the Al-Mg-Si Alloy Series

The strong and increasing need for weight reduction in transport industry, such as in automotive, rail, and aeronautics contexts, has led to a great interest and a diffuse use in aluminum sheets. In this regard, the heat-treatable Al-Mg-Si series alloys have attracted a great interest in the past three decades.^[1]

From a technological point of view, this class of heat-treatable alloys gets its final strength typically during the paint bake cycle in most of the transport and the architecture applications (in the latter case, mainly as window fixtures). As a matter of fact, in the transport and architecture application fields, this class of aluminum alloys combine the good formability of the solution-treated state (namely, a T4 temper) with the increased service strength of the age-hardened state after paint baking (usually a T6 temper, but also possibly a T8 temper).

The AA6000 series contain silicon and magnesium as referee alloying elements, although often small addition of copper, as well as other grain refining elements, such as scandium and/or zirconium, are also added. With this respect, compared to the Al-Cu AA2000 as well as the AA5000 Al-Mg series, the Al-Mg-Si sheets show better formability, better corrosion resistance, and a fairly good strengthening potential at sufficiently high exercise temperature.

As for the production processes, extrusion, as well as rolling, is the main technological processing procedure for making Al-Mg-Si (AA6000 series) components, especially in form of bars, sheets, and plates. More specifically, Al-Mg-Si are widely used for the production of thin panels, such as hood, deck-lid, and doors, but also window frames, and the like.

Al-Mg-Si alloys are also recognized as an important technology class of aluminum alloys for the production of conductive light materials. In fact, their high strength-to-density ratio, together with their good electrical conductivity, excellent formability, and good corrosion resistance make this class of alloys an interesting and actually widely used aluminum components for the electronics, and the electrical applications.

The Age-hardening Precipitation Particle Sequences and Their Mechanical Impact

The rolling and the extrusion processes are strongly influenced, and controlled, by the alloy crystallographic texture of the sheets and plates, either during the plastic deformation, or in the final T4 and T6 (sometimes also T8) temper states. It is known, and generally agreed, that a strong recrystallization texture has to be avoided so as to make possible a sound formability and to prevent the occurrence of paintbrush lines (in the case of painted sheets and plates, but also in the case of anodized surface).^[2,3] Secondary precipitation (namely, β -Mg₂Si) and iron-rich

intermetallic phases are known to affect the evolution of the crystallographic texture during plastic deformation. Thus, a control of the precipitation sequence of the hardening secondary particles offers a valuable tool for the texture optimization during the plastic deformation processes. In particular, iron and manganese do form coarse particles and considerably weaken the recrystallization texture and refine, to some extent, the grained structure after T4 temper and T6 age-hardening treatment. Anyhow, the presence of the iron-rich and iron-manganese-rich intermetallic phases is responsible for a significant ductility and formability degradation of the Al-Mg-Si alloys; for this reason, their presence in the alloy must be taken under well-fixed volume fraction limits (which is typically of within 2000–3000 ppm).^[4]

Conversely, a finely dispersion of Mg₂Si strengthening particles favor the formation and development of a strong cube recrystallization texture, which, in turn, detrimentally affect the alloy formability during extrusion or rolling.^[4] Hence, an accurate knowledge of the precipitation sequence is thus needed for sound, strength-effective, and durable Al-Mg-Si extruded and rolled sheets, planes, and bars.

The precipitation sequence during age-hardening processes of the Al-Mg-Si series alloys has been extensively studied, characterized, and described in the last three-to-four decades.^[5–16] With this respect, van Huis and coworkers,^[5,6] Myhr et al.,^[9,10] and many others identified a well detailed precipitation sequence starting from the early stages of point defect supersaturated solid solution concentration. The complete precipitation sequence of the Al-Mg-Si alloys can then be summarized as follows:

SSSS $\rightarrow$ solid solution clustering $\rightarrow$ cluster concentration and coarsening to 1–5 nm $\rightarrow$ formation (promotion) of pre-precipitate β'' $\rightarrow$ final solute concentration in β'' $\rightarrow$ late phase formation: β' , B' , U1, U2 $\rightarrow$ formation of the stable and coarser β (Mg₂Si) phase

In this sequence, SSSS stands for supersaturated solid solution in which Mg and Si atoms start to aggregate at large concentration vacancy sites. The 1–5 nm clusters have a plate-like morphology with a Si:Mg ratio of 1/2. These platelets consist of alternating column of Mg and Si atoms oriented along $\langle 100 \rangle$ crystallographic directions. The initial formation of the β'' pre-precipitate was identified to be as Mg₂Si₃Al₆.^[16] This is a pre-phase with high Al concentration (~60%), and thus the crystallographic coherency with the matrix is still quite high. During the whole sequence, the Mg and Si solute concentration steadily increases to its stoichiometric maximum in the late phase formation β' , B' , U1, U2, and, evidently in the β phase. The β' (Mg₅Si₆) constitutes the pre-precipitate particle/solute agglomeration, in the precipitation sequence with the highest Si:Mg ratio. The β'' pre-phase has a needle-like morphology, while the β' , B' , U1, and U2 all have a rod and/

or lath morphology, and the β (Mg_2Si) phase has a cubic morphology. More specifically, the hardening pre-phase β'' (whose formation yields the peak alloy hardness values) has a monoclinic structure with composition essentially unaltered with respect to the β' . The late phases (β' , B' , $U1$, and $U2$) have trigonal, hexagonal, and orthorhombic structures, respectively.

In the industrial production field, pretreatments to the T4, or T6 common bake-hardening treatments of sheets, especially in the automotive industry, are usually applied. These are intended to promote the precipitation strengthening sequence exactly at the stage of paint baking, to which generally these types of sheets are subjected during the industrial thermomechanical processing.^[17–19]

Another interesting and successful means to promote and speed up the precipitation sequence to peak age hardening is the pre-deformation (almost a T8 temper). This is also known as *deformation heat treatment method*.^[20] This practice greatly promotes the formation of microstructural defects in form of dislocations and vacancies. These, in turn, promote and accelerate the alloy precipitation sequence that is induced to form at the vacancy and line-defect sites during the following aging treatment. As a matter of fact, the pre-straining is generally mild and applied just after the solution treatment. This practice effectively induces a hardness, and yield strength increase, after T6, or T8, paint bake treatments (Ref. [21], to cite but one), or other age-hardening treatment procedures.^[22–24]

Another way to promote the age-hardening sequence and also to increase, to some extent, the Al-Mg-Si series alloy hardness and yield strength is by adding small quantities of other elements. One of the most important and effective such elements is Cu. With this respect, a large literature on the effect of copper on the age-hardening Al-Mg-Si series response can be found, especially in the last two decades.^[25–35] Indeed, a very small addition of Cu (typically within 0.1 wt%) was demonstrated to not alter the precipitation sequence and to not improve the strengthening capability of the Al-Mg-Si-(Cu) alloys.^[28] When the amount of Cu is larger than 0.1 wt%, the precipitation sequence of the Al-Mg-Si-(Cu) slightly changed to:

SSSS $\rightarrow$ solid solution clustering $\rightarrow$ cluster concentration and coarsening to 1–5 nm (generally known and accepted as G.P.) $\rightarrow$ formation (promotion) of pre-precipitate $\beta'' \rightarrow$ final solute concentration in $\beta'' \rightarrow \beta' \rightarrow$ phase formation: β' , B' , $U1$, $U2 + L \rightarrow$ formation of the stable and coarser β (Mg_2Si) phase + Q phase

In this case, the β'' pre-precipitates have a monoclinic crystallographic structure, the β' particles have a hexagonal structure, the $U1$, $U2$, and B' have an orthorhombic, trigonal, and hexagonal structure, respectively. The $U1$ and $U2$, two strengthening particles most likely to

form during aging, are also called Type A and Type B particles, respectively. Sometimes, β' particles are also called Type C particles. In addition to these particles, the presence of a small addition of Cu is responsible for the formation of the L pre-precipitate, which is a precursor of the hexagonal crystal structure phase Q ($\text{Al}_4\text{Cu}_2\text{Mg}_8\text{Si}_7$). In particular, this latter quaternary phase grows as to have its long axis oriented parallel to the $\langle 100 \rangle_{\text{Al}}$ crystallographic directions. The precursor L particles are actually hardening particles for this alloy system. In this sense, the addition of small quantities of Cu also induces a ductility improvement to the alloy and enhances the precipitation-hardening kinetics. It also affects, to some extent, the grain stability upon heating. All these beneficial effects are guaranteed by the coexistence of the two hardening particles: β''/β' and L.

High Cu content (typically in excess of 1 wt%) results in higher yield strength, especially in the T4 temper, but it has detrimental effects in the stamping, extruding, and similar high-temperature technological processes. The excess of Cu content in the Al-Mg-Si (AA6000 series alloys) is also responsible for significant, if not drastic, reduction of the corrosion resistance and weldability of the alloys. All these mechanical, microstructural, and technological aspects make the practice of Cu addition to the Al-Mg-Si alloys a non-easily controlled mean for the alloy age-hardening optimization. The Cu addition to the Al-Mg-Si series alloys has thus to be taken into consideration and pursued quite carefully.

Finally, when small quantities of Cu addition are coupled with a small fraction of Ag addition, to the Al-Mg-Si alloys (Ref. [36], to cite but one), their combined effect is to further contribute to slightly increase the age-hardenability of the alloy, through a more stable L precipitation, which can thus be considered optimized by the combined presence of Cu and Ag.

Another side effect of the thermomechanical industrial processes of the Al-Mg-Si alloys is a significant enhancement of electrical conductivity in the alloy.^[37–40] With this respect, every strain hardening practice, and thermal strengthening treatment (namely, T6, T7, and T8 tempers), is accompanied with a reduction of the electrical conductivity properties of the treated alloy that can also be significant.^[37,38] The alloy electrical conductivity reduction is due to the occurrence of the matrix lattice distortion, by the introduction of point and line defects (alloy straining), and the introduction of crystal lattice volume distortion and composition discontinuity (alloy strengthening thermal treatments). In the case of alloy strengthening by thermal treatments, a good practice to maintain a sufficiently high electrical conductivity of the alloy is to prolong the typical T6 and T8 thermal treatments to an overaged state. This practice would induce an alloy strengthening reduction, but, in fact, constitutes a good and sound optimization between strengthening and electrical conductivity. In this sense, recently Valiev and coworkers^[41] have proved that

high-pressure torsion (i.e., by SPD) is likely to guarantee a proper optimization of tensile strength and electrical conductivity of Al-Mg-Si alloys.

Irrespective of the specific application fields and peculiar mechanical, physical, and conductivity properties that are intended to be tailored in the Al-Mg-Si alloy series, the presence of iron-rich intermetallic phases is always detrimental. In the Al-Mg-Si series, the intermetallic phases that generally form are of the types: $\alpha = \text{Al}_8\text{Fe}_2\text{Si}$, $\beta = \text{Al}_5\text{FeSi}$, and $\pi = \text{Al}_9\text{FeMg}_3\text{Si}_5$ (or alternatively $\text{Al}_8\text{FeMg}_3\text{Si}_6$).^[42–44] The formation of the α and β coarse intermetallic phases (generally few micron-long needle-like particles) is always accompanied by a significant yield, ultimate strengths, and a drastic ductility reduction. The α and β intermetallic phases form during the alloy solidification. These act as stress raisers and become points of weakness for the alloy. Moreover, these are hard to dissolve during the homogenization treatments. It is thus good practice to minimize the iron alloy content, thus reducing the occurrence of the iron-rich intermetallic phase formation to an acceptable amount. The π phase generally forms lamellar arrays distributed as to create a Chinese script-like structure. This is particular detrimental in the cast Al-Mg-Al alloys. They are likely to form where the β intermetallic phases were located and partially, or entirely, induced to dissolve during the heat treatments. The π intermetallic phase is likely to be promoted in the post-solidification heat treatments, to which the age hardening plastically deformed Al-Mg-Si alloys are subjected.

Quite different microstructure effects are related to the addition of small percentage fraction of zirconium and/or scandium. The major beneficial role of the Zr and Sc addition to the Al-Mg-Si series includes mechanical strength increment, better creep resistance, and improved corrosion resistance.^[45]

These two elements are added in the wrought alloys. During solidification, very fine, highly stable, Al_3Zr , Al_3Sc , or $\text{Al}_3(\text{Sc}, \text{Zr})$ rounded particles are induced to form. They act as nuclei for heterogeneous nucleation of the strengthening secondary particles and as grain refiners.^[46–48] All these beneficial effects are favored by the very fine size and spherical morphology of the Sc- and Zr-containing dispersoids that promote the Si particles spheroidization, a precipitation strengthening temperature–time optimization, and a grain boundary pinning effect.

Role of SPD

In the last decades, the SPD practice of aluminum alloys has been widely and successfully applied.^[49–59] Different SPD techniques have been extensively tested, and these include equal-channel angular pressing (ECAP), high-pressure torsion (HPT), and accumulative roll bonding. In all these three processes, significant grain refinement is achieved in virtually all the aluminum alloy

series. In particular, ECAP and HPT applied to Al-Mg-Si are able to produce an ultra-fine grained structure. This is also accompanied by a great fraction of induced tangled dislocations and low-angle boundary (LAB) cells. The subsequent strengthening heat treatment, or even the high-temperature SPD, is strongly affected by the SPD process that generally induces a complex strengthening precipitation sequence.

Hence, the advantages of fabricating severe plastically deformed (SPD) materials with submicron sized grains as structural components lie in their improved mechanical properties such as strength, hardness, ductility, fatigue resistance, and sometimes to a low-temperature superplasticity.

Modeling of alloy strengthening evolution during and after SPD, namely, ECAP, in the Al-Mg-Si alloy series was proposed and proved in some recent publications,^[10,11,60–63] including two by the present author.^[62,63]

It results that the SPD is able to tailor and optimize the strengthening precipitation sequence, the grain strengthening, as Hall–Petch contribution, and the solid solution contribution to the Al-Mg-Si alloy yield stress. This is also improved whenever Sc and Zr are added in the Al-Mg-Si alloys.

With this regards, in the following, two case studies are reported: in the first, a strengthening model of ECAP Al-Mg-Si alloy is proposed; the second describes an ECAP-induced strengthening and precipitation model in a Al-Mg-Si-Zr-Sc alloy subjected to ECAP and T6 temper (overaged state).

FIRST CASE STUDY

Al-Mg-Si alloy Subjected to ECAP

ECAP is an especially attractive processing method because it allows large bulk samples to be produced, which are free from any residual porosity, and are subjected to small shape changes. The evolution of the microstructure during ECAP is closely driven by the specific pressing conditions, i.e., by the shearing deformation induced in the material at each pass through the die.^[51,57,64] Plastic deformation of metals occurs as a result of the formation, movement, and storage of dislocations. In fact, microstructure evolution during ECAP is directly linked to a complex dislocation evolution into networks and to dislocation recombination and annihilation phenomena. During shearing deformation, the evolution and accumulation of misorientation across both LABs and high-angle boundaries (HABs) is closely related to the crystallographic accommodation of each crystallite with its neighboring crystallites.^[65] In deformation route B_C , a rotation of $+90^\circ$ per passes is induced, route C implies a 180° billet rotation per pass, and route A does not involve any sample rotation.^[51,59,64–66] Whatever the route used,

ECAP has extensively been reported to induce a severe microstructure refinement already at the earliest imposed strain levels.

In this context, Niels Hansen (Ref. [54] and references therein) has extensively developed a modified Hall–Petch relationship, where the yield strength is the linear sum of the friction stress term plus the dislocation boundary contribution (LAB) and the grain size contribution (HAB).

Since then, other different approaches to the modeling of the proof stress from the microstructure strengthening contributions were also proposed.^[67–73] It was thus exhaustively documented that dislocation sliding is the major deformation mechanism ultimately responsible for the most part of the material proof stress. In particular, analytical estimation approaches for the grain strengthening contribution determination are proposed, and these are based on the concept of grain size diversity, which depends on a dimensionless coefficient of variation of grain size distribution. This approach has many similarities and analogies with the phase-mixture model developed by Estrin et al. to explain the mechanical properties of nanocrystalline alloys.^[74,75]

In the case study, the modified Hall–Petch approach is further extended to include strengthening contributions from solid solution, contributions yield by secondary-phase particles, and contributions coming from the very LABs, typically showing Moiré fringes and not detected by conventional electron backscattered diffraction maps, from LABs, and from HABs. Texture contribution and other microstructure issues, which are likely to contribute to the alloy strengthening, are also taken in consideration.

The present case study refers to the Al-Mg-Si series alloy, whose composition is as follows: 1.19Mg, 1.02Si, 0.65Mn, 0.27Fe, 0.10Cr, 0.015Ti, 0.005Cu, and Al bal. (AA6082).

This alloy was subjected to ECAP at room temperature. Cylindrical bars were pressed into the ECAP die with forces ranging between 40–80 kN and a pressing speed of 40 mm/min. The ECAP die consisted of two blocks of SK3 tool steel (Fe-1.1%C), which were bolted together to give an L-shaped channel with a circular cross section of 10 mm in diameter, consisting of two linear parts intersecting at an angle $\Phi = 90^\circ$ with a curvature extending over an angle $\Psi = 20^\circ$. With this die configuration, a true strain of $\varepsilon = 1.08$ was imposed to the specimens at each pass.^[66] ECAP was carried out using the so-called route B_C, that is a +90° billet rotation at each ECAP pass, up to an equivalent strain of $\varepsilon = 6.48$ (6 passes). The alloys were subjected to ECAP in a T6 temper state.

The microstructure strengthening contribution are thus determined as follows:

The aluminum matrix term is $\sigma_{\text{pure Al}} = 10 \text{ MPa}$,^[62] which refers to un-textured, undeformed, and very coarse-grained pure aluminum.

A simplified strengthening contribution model is generally agreed for the alloy solid solution. This is expressed as a power law relationship between the mean element solute concentration, c , and the matrix as follows:

$$\Delta\sigma_{\text{ss}} = Ac^p \quad (1)$$

where A is a constant related to the size, modulus, and electronic mismatch between the solute atoms and the aluminum matrix, and the exponent $p = 2/3$.

As for the alloy strengthening contribution coming from the secondary phase particles, these have to be distinguished in non-shearable and shearable particles by the sliding dislocation.

Non-shearable (bypassed) secondary phase particles contribute to the alloy strengthening through the Orowan strengthening mechanism, $\Delta\sigma_{\text{Orowan}}$, as, Eq. 2:

$$\Delta\sigma_{\text{Orowan}} = \frac{KM}{(1-\nu)^{1/2}} \frac{Gb}{\lambda_p^{n-s}} \ln(3\pi b/4d_p^{ns}) \quad (2)$$

where $K = 0.127$, ν is the Poisson's ratio ($=0.331$), the apex ns stands for non-shearable particles, d_p^{ns} is the mean particle size, and λ_p^{ns} is their mean interparticle spacing.

The shearable (cut) particle contribution is described by the antiphase boundary (APB) strengthening mechanism that depends on the particle morphology. For spherical-shaped particle this is, $\Delta\sigma_{\text{shear}}(\text{Si particles})$, Eq. 3a:

$$\Delta\sigma_{\text{shear}}(\text{Si}) = \left(\frac{\gamma}{2b} \right) \left[\left(\frac{4f_p^s}{\pi} \right)^{0.5} - f_p^s \right] \quad (3a)$$

where γ is the APB energy, f_p^s is the shearable particle volume fraction, and the apex s stands for the shearable particle.^[76]

The shearable needle-like particle contribution, $\Delta\sigma_{\text{shear}}(\beta')$, and eventually β , is, Eq. 3b:

$$\Delta\sigma_{\text{shear}}(\beta') = (\phi e)^{1.5} GM \left(\frac{3d_p^s f_p^s}{4\pi b} \right)^{0.5} \quad (3b)$$

where ϕ is a constant (whose value typically vary between 3 and 4), f_p^s is the particle volume fraction, d_p^s is the particle mean size, and $e = \frac{\delta}{(3 + 2E/B(1 + \nu))}$, in which δ is the particle atomic volume and B is the particle bulk modulus) is the particle misfit parameter.^[76]

A further strengthening term due to the presence of the dispersoids is also taken into account. This strengthening term, according to Hazzledine,^[77] is expressed in the following equation:

$$\Delta\sigma_d = \frac{MGB}{d_d} \left(\frac{6f_d}{\pi} \right)^{1/2} \quad (4)$$

where d_d and f_d are the dispersoids particle size and volume fraction, respectively.

The overall secondary phase particle contribution, $\Delta\sigma_{spp}$, can be added according to the Ardell model, Eq. 5:^[78]

$$\Delta\sigma_{spp}^{1.4} = \sum \Delta\sigma_{shearable}^{1.4} + \left[\left(\sum \Delta\sigma_{non_shearable}^2 \right)^{0.5} \right]^{1.4} \quad (5)$$

As regards the intermetallic particle strengthening contribution, according to the shear-lag model proposed by Nardone and Prewo,^[79,80] the composite particles are found to contribute to alloy reinforcement carrying a fraction of the load from the matrix, $\Delta\sigma_{LT}$:

$$\Delta\sigma_{LT} = \sigma_0 \left[1 + \left(\frac{(L+t)A}{4L} \right) f_{inter} \right] \quad (6)$$

where f_{inter} is the intermetallic particle volume fraction, L is the mean particle size facing the load direction, t is the mean particle thickness, and $A = L/t$ is the particle aspect ratio.

The dislocation boundary strengthening can be modeled as follows:

$$\begin{aligned} D\sigma_{LAB} &= M\alpha Gb (\rho_0 + \rho_{LAB})^{1/2} \\ &= M\alpha Gb\rho_0^{1/2} + M\alpha G \left[(3b\theta_{LAB}(1-f_{HAB}))^{1/2} \right] d_{HAB}^{-1/2} \end{aligned} \quad (7a)$$

$$\Delta\sigma_{HAB} = kd_g^{-1/2} = M\alpha G \left[k_{HAB} f_{HAB}^{1/2} \right] d_{HAB}^{-1/2} \quad (7b)$$

$$\Delta\sigma_{Moiré} = M\alpha G \left(\frac{3b\theta_{Moiré} f_{Moiré}}{d_{Moiré}} \right)^{1/2} \quad (7c)$$

where M ($=3.07$) is the Taylor factor of un-textured aluminum, α is a constant ($=0.24$), G is the shear modulus (26 GPa, for aluminum), b is the Burgers vector (0.286 nm, for aluminum), ρ_0 is the dislocation density between the boundaries, $\rho_{LAB} = 3(1-f_{HAB})\theta_{LAB}/(bd_{HAB})$ is the dislocation density stored in the low-angle dislocation boundaries, whose strengthening contribution refers to the dislocation forming the cell structure, $d_g = d_{HAB}/f_{HAB}$ is the average spacing of boundaries that contribute as grain boundary strengthening, $k_{HAB} = 40 \text{ MPa}\mu\text{m}^{1/2}$.

Figure 1 shows a representative example of a very low-angle boundary (showing Moiré fringes), and LAB/HAB.

In general, *f.c.c.* metals have fewer primary slip systems, which are $\{111\}<110>$. In fact, the high stacking fault energy of Al makes dislocation slip on $\{111\}$ planes the only deformation mechanism.

To model the texture strengthening of ECAP aluminum alloys, the approach used by Estrin et al.^[81] was adopted. Simple shear deformation, as in ECAP, was

Fig. 1 Micrograph showing very low-angle boundaries producing Moiré fringes on TEM

found to induce a continuous parabolic reduction in the Taylor factor with strain, from $\varepsilon \cong 0.5$ to $\cong 13$, and strain rate sensitivity ranging $4 \cdot 10^{-3}$ to $2 \cdot 10^{-2}$. The Taylor factor reduction, in the range $\varepsilon \cong 0.5$ to $\cong 13$, accounts for 10% of the undeformed state.

Model Validation

In the following, the data referring to the secondary phase particles, dispersoids, very-low, low-, and high-angle boundary distribution, obtained by TEM inspections are reported. These data, applied to the present model, are indeed able to properly describe the yield stress of the ECAP Al-Mg-Si AA6082.

The mean solute element concentration, $c_{ss,element}$, can be determined according to a lever rule,^[76] Eq. 8:

$$c_{ss,element} = (c_{t,element} - f_p c_p) / (1 - f_p) \quad (8)$$

where $c_{t,element}$ is the total alloy amount of the considered element, f_p and c_p are, respectively the fraction and concentration of the element inside the existing secondary phase particles (if any).

Table 1a reports the strengthening contribution of each solute element in the six alloys at the different shearing deformation levels.

Table 1b reports the TEM quantitatively evaluated values used to determine the non-shearable, and the shearable particles, the dispersoids, and the intermetallic phase strengthening contributions.

Table 1c reports all the quantitative microstructure data, obtained by the TEM analyses, and used to determine the dislocation contribution to the alloy yield strength, $\Delta\sigma_{dislocation}$, according to Eq. 7a–c.

Table 1a Strengthening contribution of the alloy solute atoms

ECAP strain	$\Delta\sigma_{Mg} = 20.5 \cdot c_{ss,Mg}^{2/3}$ (MPa)	$\Delta\sigma_{Si} = 66.4 \cdot c_{ss,Si}^{2/3}$ (MPa)	$\Delta\sigma_{Mn} = 15.8 \cdot c_{ss,Mn}^{2/3}$ (MPa)	$\Delta\sigma_{Al_{12}(Fe,Mn)_3Si}$ (MPa)	Solute strengthening contribution (MPa)
$\varepsilon = 1.08$	2 ± 1	8 ± 1	3 ± 1	11 ± 1	24 ± 2
$\varepsilon = 4.32$	3 ± 1	12 ± 1	3 ± 1	11 ± 1	29 ± 2
$\varepsilon = 6.48$	6 ± 1	18 ± 1	3 ± 1	11 ± 1	38 ± 2

Table 1b Input data, obtained by the TEM inspections and analyses, used to calculate the shearable, un-shearable secondary phase, dispersoid particle, and intermetallic phase strengthening contributions, according to Eqs. 2–6

	d_p (nm)	f_v^p 10^3	λ_p (μm)	d_p (nm)	f_v^p 10^3	λ_p (μm)	λ_p^* (μm)	f_{inter}	L/t (μm)	Intermetallic strengthening contribution (MPa)	Particle strengthening contribution (MPa)
	Si			Mg ₂ Si			0.30 14 / 1			21 $\pm$ 4	
$\varepsilon = 1.08$	119	10	0.58	151	100	0.17	0.075				103 $\pm$ 10
$\varepsilon = 4.32$	110	10	0.61	133	24	0.38	0.152				63 $\pm$ 6
$\varepsilon = 6.48$	102	10	0.57	108	22	0.33	0.133				52 $\pm$ 5

d_p is the mean size, f_v^p is the volume fraction, λ_p is the mean spacing, and λ_p^* is the mean particle spacing weighted with respect to the volume fraction of all the secondary phase particles within the matrix. For the intermetallic phase particles: f_{inter} is the volume fraction, L is the mean size facing the load direction (which is the long broader surface edge of the existing intermetallic phases), t is the mean thickness, and $A = L/t$. The strengthening contributions are reported in the last two columns.

Table 1c Mean Moiré fringe boundary angle misorientation, $\theta_{Moiré}$, LAB misorientation angle (short of the Moiré fringe boundary angle population), $\theta_{LAB-Moiré}$; Moiré boundary, LAB-Moiré and HAB volume fraction, $f_{Moiré}$, $f_{LAB-Moiré}$, f_{HAB} ; mean Moiré boundary and HAB spacing, $d_{Moiré}$, d_{HAB} , as a function of ECAP strain. The overall boundary strengthening contributions is reported in the last column, according to Eq. 7

	ECAP strain	$\theta_{Moiré}$ (°)	$f_{Moiré}$	$d_{Moiré}$ (μm)	$\theta_{LAB-Moiré}$ (°)	$f_{LAB-Moiré}$	d_{HAB} (μm)	f_{HAB}	Dislocation strengthening contribution (MPa)
AA6082	$\varepsilon = 1.08$	3.8	0.20	0.38	5.2	0.54	3.42	0.27	178 $\pm$ 9
B _c	$\varepsilon = 4.32$	4.4	0.11	0.22	7.9	0.27	1.06	0.63	229 $\pm$ 11
	$\varepsilon = 6.48$	4.5	0.07	0.11	8.5	0.16	0.94	0.78	228 $\pm$ 11

The strengthening contribution due to texture is modeled through the Taylor factor modification with accumulated strain,^[62] and the corresponding values are reported in Table 2.

The total strengthening microstructure contribution comes from a proper combination of the different microstructure terms: solid solution, $\Delta\sigma_{ss}$, very-low- (showing Moiré fringes on TEM), low- (LAB), and HABs, $\Delta\sigma_{dislocation}$, secondary phase, $\Delta\sigma_{particles}$, dispersoids, $\Delta\sigma_d$, and intermetallic phase particles, $\Delta\sigma_{LT}$, (texture being considered via the Taylor factor variation with strain). A simple linear superimposition, Eq. 9, has been proved to show the best fit to the experimental data, respect to other combination models;^[62,82,83]

$$s_y = s_0 + Ds_{ss} + Ds_{dislocation} + Ds_{particles} + Ds_d + Ds_{LT} \quad (9)$$

Table 2 Taylor factor values, M , as a function of ECAP strain; the un-textured aluminum is $M = 3.07$

ε	1.08	2.16	3.24	4.32	5.40	6.48	8.64	12.96
M	3.01	2.95	2.92	2.88	2.86	2.82	2.79	2.76

Note: The reported values are not affected by the specific route used.

The soundness of the model and the linear combination of all the strengthening terms can be inferred from Fig. 2, where this strengthening model well describe the alloy yield stress as obtained by direct tensile tests.

An interesting microstructure aspect of the ECAP applied to the Al-Mg-Si series alloy is the induced phenomena of dislocation cut and partial dissolution of the β''/β' and Si particles, respectively. Figure 3 reports a representative TEM image of such microstructure ECAP-induced phenomena.

SECOND CASE STUDY

ECAP of Al-Mg-Si Alloy Containing Grain Refiners (Sc and Zr)

The requirement of a small and stable grain size is usually achieved by using either two-phase alloys or materials containing precipitates that reduce grain boundary mobility and thereby restrict grain growth. The latter is a specific peculiarity of Sc–Zr containing dispersoids that are able to effectively pin low and high angle boundaries together with

Fig. 2 Yield stress vs. mean grain size obtained by applying the model described in the first case study, which is compared to the values obtained experimentally by tensile tests

Fig. 3 Representative TEM showing the ECAP-induced cutting of β' and partial dissolution of Si particles (Al-Mg-Si AA6082 subjected to ECAP-B_C/8 passes, equivalent to $\epsilon = 8.64$)

free dislocations. Aluminum alloyed with scandium and/or zirconium has excellent mechanical properties at room temperature, due to the presence of nanometer coherent Al_3Sc , Al_3Zr , and $\text{Al}_3(\text{Sc},\text{Zr})$ dispersoids that are effectively dispersed either in the grain boundaries and within grains, thus blocking mobile dislocations and stabilizing a fine-grained structure^[48,84] (Fig. 4). When Sc and Zr are both added to the alloy, Zr is able to replace some of the Sc in Al_3Sc , giving rise to $\text{Al}_3(\text{Sc}_{1-x},\text{Zr}_x)$ dispersoids having an L12 crystal structure like the Al_3Sc . Loss in coherency of either Al_3Zr and $\text{Al}_3(\text{Sc}_{1-x},\text{Zr}_x)$ dispersoids has been documented to promote an increase in particle coarsening rate and in their spacing. This effect produces a decrease in the dispersoids pinning efficiency against boundary migration

Fig. 4 Shear deformation induced by ECAP in presence of $\text{Al}_3(\text{Sc},\text{Zr})$, in an Al-Mg-Si-Sc-Zr alloy subjected to ECAP-B_C/4 passes ($\epsilon = 4.32$)

and dislocation sliding.^[85,86] The typical radius for coherent-to-semicoherent dispersoids transition is in the range 15–40 nm.

The present second case study reports on the microstructure strengthening effect of two Al-Mg-Si (AA6106) alloys, one added with 0.10 wt%Zr, and the second added with 0.10 wt%Zr and 0.12 wt%Sc. Both alloys were subjected to ECAP at room temperature. ECAP configuration was the same as the one used in the previous case study. The used route was still the B_C, this time extended to an equivalent strain of 12.96, corresponding to 12 ECAP passes. The alloys were subjected to ECAP in a T6 temper state to an overaged condition.

In the Al-Mg-Si-Zr alloy, the Al_3Zr dispersoids are mostly coherent and spherical, which are heterogeneously distributed throughout the matrix. In the Al-Mg-Si-Zr-Sc alloy, the $\text{Al}_3(\text{Sc}_{1-x},\text{Zr}_x)$ dispersoids are significantly more homogeneously distributed. Figure 5(a–c) reports the mean misorientation of cell (Fig. 5a) and grain boundaries (HABs) (Fig. 5b) as a function of the strain, while Fig. 5c shows the fraction of the HABs versus cumulative strain. Data were obtained from TEM inspections and applying the strengthening model and approach, described in the first case study. In particular, the effect of the $\text{Al}_3(\text{Sc}_{1-x},\text{Zr}_x)$ dispersoids, during ECAP, results in the higher increasing rate of misorientation of both HABs and LABs, as they induce a greater boundary misorientation rise compared to what happens when the alloy contains the Al_3Zr dispersoids. The deformation and microstructure refining mechanism is believed to be greatly influenced by the spatial distribution and size of the fine dispersoids. In fact, they act as preferential deforming paths for the deformation bands, which control the refining process. Both HABs and LABs, which were generated during ECAP, are made to flow and slide

Fig. 5 Misorientation evolution with cumulative ECAP strain for both Al-Mg-Si-Zr and Al-Mg-Si-Sc-Zr referring to (a) cell (LABs), (b) grain boundary (HABs), and (c) HAB fraction evolution

within the microstructure by the effect of the specific die geometry, and shearing path at an angle of $\sim 45^\circ$ with respect to the pressing direction, as is the case of aluminum alloys not containing dispersoids.^[54,87–90] In fact, boundaries evolution is sensitive to the fine dispersoids spatial distribution. More specifically, in the present study, both alloys showed

a nonuniform dispersoids distribution, in that they are primarily located along rows almost parallel to the extrusion direction of the bars. Thus, dispersoids lying along the formed extruded direction pin the newly formed boundaries. The combination of the strong boundary pin capability and their preferred spatial distribution is able to generate a quick misorientation increment, at each strain leap, especially on the previously generated boundaries. As a consequence, the larger fraction of HABs and LABs of the Al-Mg-Si-Zr-Sc alloy, compared to the alloy containing Al_3Zr dispersoids, is generated by the continuous misorientation increment driven by the $Al_3(Sc_{1-x},Zr_x)$ dispersoids.

In the previous case study, a strong influence of the high dislocation density, introduced during ECAP, on the secondary phase particles distribution was documented. In addition, a partial redistribution of Mg and Si atoms within the Al-matrix from the long, needle-like β' - Mg_2Si particles (which were cut off by the glide dislocations), and from the partial dissolution of the rounded Si particles was also induced by the ECAP.

In this case study, where the Al-Mg-Si alloy also contains Zr- and Zr-Sc- dispersoids, their role is to inhibit the effect of dislocations in cutting and partially dissolving Mg_2Si and Si particles, respectively. The Al_3Zr and $Al_3(Sc_{1-x},Zr_x)$ dispersoids effectively pin the sliding dislocations and LABs, thus leaving a small fraction of them free to act on the secondary phase particles. Another interesting aspect of the presence of the Al_3Zr and $Al_3(Sc_{1-x},Zr_x)$ dispersoids is the significant alloy fatigue resistance increment that is induced in the alloy by their grain boundary pinning effect.^[91]

Model Validation

Thus, Table 3a, 3b, 3c report the strengthening contributions given by the alloys solid solution, the ones coming from the hardening secondary phase particles (namely, Si nanometric particles, and β'), and the complex strengthening contributions coming from the different dislocation boundaries (i.e., the very low-, low-, and high-angle boundaries). The rather low density of fine particles of Si and Mg_2Si secondary phase is basically due to the over-aged temper ($190^\circ C/8$ h), which induced a bulky particle growing to a size range of hundreds of nanometer. These were not taken into account in the Orowan strengthening calculations as a function of strain due to their far less effectiveness in alloy hardening.

Figure 6 shows the overall microstructure strengthening of both the Zr- and the Sc-Zr-containing Al-Mg-Si alloys. The continuous yield stress rise with cumulative ECAP strain, namely, with cell (LABs) and grain (HABs) size reduction, is evident for both the alloys. More specifically, the stress increment with grain size reduction is significantly larger for the Al-Mg-Si-Sc-Zr alloy, with respect to the Al-Mg-Si-Zr. This indeed shows how more

Table 3a Solid solution strengthening contribution of the Al-Mg-Si-Zr and Al-Mg-Si-Sc-Zr alloys

ECAP strain	$\Delta\sigma_{Mg} = 20.5 \cdot c_{ss,Mg}^{2/3}$ (MPa)	$\Delta\sigma_{Si} = 66.4 \cdot c_{ss,Si}^{2/3}$ (MPa)	$\Delta\sigma_{Mn} = 15.8 \cdot c_{ss,Mn}^{2/3}$ (MPa)	$\Delta\sigma_{Al_{12}(Fe,Mn)_3Si}$ (MPa)	Solute strengthening contribution (MPa)

	$\varepsilon = 12.96$										110 ± 11

Note: d_p is the mean size, f_v^p is the volume fraction, λ_p is the mean spacing, and λ_p^* is the mean particle spacing weighted with respect to the volume fraction of both strengthening secondary phase particles within the matrix. For the intermetallic phase particles: f_{inter} is the volume fraction, L is the mean size facing the load direction (which is the long broader surface edge of the existing intermetallic phases), t is the mean thickness, and $A = L/t$. The strengthening contributions are reported in the last two columns.

effective is the strengthening contribution of the $Al_3(Sc,Zr)$ dispersoids, with respect to the Al_3Zr dispersoids (with same size range).

SUMMARY

In order to give an insight into the importance, role, and mechanism of alloy yield stress increase of the SPD techniques applied on Al-Mg-Si alloy series, in this article, two case studies are presented:

1. Strengthening model of ECAP Al-Mg-Si alloy series.
2. Strengthening role of Zr e Sc in two Al-Mg-Si alloy subjected to ECAP.

Both case studies are based on ECAP-induced microstructure strengthening over the age-hardening contribution of the secondary phase particles, and, specifically in the second case study, the ECAP grain refining evolution and potentials in presence of Zr- and Sc-Zr-containing dispersoids.

The first case study shows how an SPD technique, such as ECAP, can strongly improve the microstructure

Table 3c Mean Moiré fringe boundary angle misorientation

	ECAP strain	$\theta_{\text{Moiré}}^{\circ}$	$f_{\text{Moiré}}$	$d_{\text{Moiré}}^{\mu\text{m}}$	$\theta_{\text{LAB-Moiré}}^{\circ}$	$f_{\text{LAB-Moiré}}$	$d_{\text{HAB}}^{\mu\text{m}}$	f_{HAB}	Dislocation strengthening contribution (MPa)

The overall boundary strengthening contributions is reported in the last column.

Fig. 6 Yield stress vs. mean grain size obtained by applying the model described in the first case study plotted together with the values obtained experimentally by tensile tests for both Al-Mg-Si-Zr and Al-Mg-Si-Sc-Zr alloys

strengthening of Al-Mg-Si series alloy. The second case study represents a further important microstructure aspect of Al-Mg-Si alloys subjected to SPD; it shows the combined effect of shear deformation (ECAP) and grain boundary pinning nanometric dispersoids, namely, Al_3Zr , in one Al-Mg-Si-Zr alloy, and $\text{Al}_3(\text{Sc},\text{Zr})$, in a second Al-Mg-Si-Sc-Zr alloy.

For both cases, analytical models and experimental validations to Al-Mg-Si series alloys are presented and described.

Analytical Techniques for Aluminum

Alexis Deschamps

Institut National Polytechnique de Grenoble, Domaine Universitaire, Saint Martin d'He'res, France

Abstract

This article provides a guideline for selection of analytical methodologies for aluminum precipitates. These methodologies include: crystallographic structure, precipitate size, volume fraction, atom probe tomography, compositional chemistry, precipitation sequence, second phase particle characterization, and geometrical information analysis.

Keywords: Atom probe tomography; Differential scanning calorimetry; Optical microscopy; Transmission electron microscopy; X-Ray.

Many of the mechanical properties of aluminum alloys are obtained through the presence of precipitates. This can be in a favorable way, as precipitation hardening by a fine dispersion of particles, or control of the grain structure by the presence of dispersoids. But second phase particles can also control the properties in an unfavorable way, when iron or silicon-containing particles limit the fatigue life or the toughness of alloys.

In any case, the need for a detailed characterization of these precipitates is obvious if a good control and optimization of the process routes of aluminum alloys is to be obtained. This is of course a very complex task. First of all, precipitation characterization does not mean much by itself. The level of detail to be sought and the type of techniques to be used can be determined only if one decides the scale of the precipitates and the type of information that one needs.

- The scale of precipitates depends very much on the type of precipitate family. Typically, second-phase particles (non-soluble intermetallics) are larger than 1 μm , dispersoids are of the order of 100–500 nm, heterogeneous precipitates (e.g. on grain boundaries) are of the order of 10–50 nm, and homogeneous precipitates of the order of 2–10 nm. These vastly different scales demand different characterization techniques. Moreover, the different scale of these precipitates families is accompanied by vast differences in precipitate volume fraction: homogeneous precipitates can have volume fractions larger than 4%, whereas intermetallics usually show volume fractions of the order of 0.1%.
- A complete determination of the precipitation structure in a single sample would be an formidable task. Usually a few parameters have to be chosen, which are relevant for the property to be understood, and will dictate the choice of techniques. These information include size (and

possibly geometry), volume fraction, crystallographic structure, chemistry, distribution in space.

This chapter will try to constitute a guideline for choosing adapted experimental techniques for various problems. It will outline the possibilities and limits of numerous experimental techniques, from simple ones to implement (such as resistivity), to highly specialized experiments which can be performed only in a few laboratories in the world (such as the Tomographie Atom Probe).

This chapter will be divided in two main parts:

- characterization of hardening precipitates. The main characteristics of these precipitates are their small size ($D < 20$ nm), relatively simple geometry (sphere, rod, disk...) and high volume fraction (generally $>1\%$).
- characterization of second-phase particles. Their main characteristics are their heterogeneous dispersion, large size, low volume fraction and very complicated shape.

CHARACTERIZATION OF HOMOGENEOUS HARDENING PRECIPITATES

Crystallographic Structure

The characterization of the crystal structure of very small precipitates (nanometer size) is often not an easy task: it is difficult to obtain the crystallography of one single precipitate as the spacing between precipitates is very small. Actually, the procedure is quite different if the precipitates are presumed to be of one known structure and the aim is to check this, or if the aim is the complete determination of the structure of an unknown precipitate. In any case, by far the most widespread technique to achieve this is Transmission Electron Microscopy, since it enables to obtain simultaneously the

image of precipitates and their diffraction patterns, ensuring in this way that the diffraction spots observed are actually generated by the hardening precipitates.

In the first case, the complete structure (including space group, lattice parameters and atom positions) of the presumed precipitate can be found from crystallography books.^[1] The first task is to check if the diffraction patterns are compatible with this structure. Then it may be of interest to determine if there are any orientation relationships between the matrix and the precipitates.

The Al-Zn-Mg-Cu (7XXX) system can be taken as an example. Precipitation in this system starts by GP zones, which cannot be normally imaged in diffraction patterns since they have the same structure as the aluminum matrix. These GP zones are then replaced by η' precipitates, which are platelets lying coherently on the (111) planes of the aluminum matrix. Until recently,^[2] the complete structure of η' had not been resolved, due to their very small thickness: it was presumed that they were hexagonal with their basal plane parallel to (111), but other structures were proposed as well. However, the determination of the type of precipitate was still possible, since their signature in the $[111]_{\text{Al}}$ diffraction pattern was well known,^[3] as shown in Fig. 1a: a diffuse spot in the center of the spots (000), (220) and (2-20) of aluminum, ensuring complete coherency with the matrix on the basal plane and resulting in a lattice parameter $a = 4.96 \text{ \AA}$.

The equilibrium phase of this system is η (which in the ternary system Al-Zn-Mg is MgZn_2). Its complete structure is known, the lattice parameters are $a = 5.14 \text{ \AA}$ and $c = 8.6 \text{ \AA}$. However, a great number of orientation relationships between the precipitates and the matrix can be observed,^[4] depending notably on the type of nucleation site (in the bulk, on dislocations, grain boundaries, dispersoids, etc.). These different types of orientation relationships (which are noted as η_1, η_2 , etc.) can be distinguished from the location of their diffraction spots, for instance on the $[111]_{\text{Al}}$ diffraction pattern again (Fig. 1).^[3] In this case, one can clearly distinguish the presence of the η_2 and η_4 variants.

This type of diffraction pattern analysis applies to most of the aluminum hardening systems. Examples of analysis on various systems can be found in the literature for Al-Mg-Si-Cu,^[5,6] Al-Cu-Mg,^[7] Al-Li based alloys,^[8,9] etc.

High Resolution Electron Microscopy can also provide useful information, since this technique enables the spatial resolution of the atomic columns. From such images, one can obtain information such as lattice parameters or coherency strains between precipitate and matrix. Figure 2 shows a HREM image of a β'' precipitate in an Al-Mg-Si-Cu alloy.

The complete determination of the structure of unknown precipitates is a much more complicated task. Most precipitates have a complicated structure and large lattice parameters, thus the combination of several diffraction and imaging techniques is necessary, and some simplifications have to be made (e.g. the determination

Fig. 1 $[111]$ Diffraction patterns of the aluminum matrix in an Al-Zn-Mg alloy showing diffraction spots for the precipitates, (a) Most precipitates are of the metastable η' phase; (b) most precipitates are of the stable η phase in the η_1, η_2 and η_4 variants

Fig. 2 High resolution electron micrograph of a β'' precipitate in an Al-Mg-Si-Cu alloy in the T6 condition (Courtesy of P. Donnadieu, LTPCM, France)

will be much more difficult if several phases are present in the same sample). The point group of the precipitates can be determined by symmetry analysis of dark field High Resolution TEM micrographs. A good example of

structure determination is the work of Donnadieu et al. On alloy 6056 (Al-Mg-Si-Cu) in T6 condition.^[2,5] Through a combined use of DSC, diffraction patterns and dark field HREM in the TEM, the authors were able to determine that the precipitates were of the 2/m 2/m 2/m point group (orthorhombic structure), with lattice parameters $a = 0.8$ nm, $b = 1.1$ nm and $c \sim 0.6$ nm. An other good example of structure analysis using HREM is the work of Edwards and co-workers^[10] on alloy 6061.

Precipitate Size

The determination of precipitate size and its evolution with process conditions is extremely important for the understanding of the final properties of the material. Most obviously, in most precipitation hardening materials, a critical size of precipitates provides the highest level of yield strength. Two main methods enable the determination of precipitate size: small-angle x-ray or neutron scattering provides an average indirect measurement on a very large population of precipitates, and Transmission Electron Microscopy provides a local direct measurement, but with poorer statistics.

X-ray and Neutron Scattering

The principle of Small-Angle x-ray or Neutron Scattering (SAXS and SANS) is simple. We consider a material containing two phases which have a different electronic density (for SAXS measurements), a matrix and precipitates. X-rays traversing the sample are scattered by these precipitates, and the intensity as well as the angle at which this scattering occurs depends on the size of the precipitate, the electron density contrast between the precipitates and the matrix, and the volume fraction of the precipitates. Thus, a detailed study of the scattered spectrum can provide useful information on the size of the precipitates, and a relationship between their composition and volume fraction.^[11]

SAXS can be performed with a variety of x-ray sources. They range from cheap and easy to handle x-ray tubes (used as well in diffractometers), more powerful rotating anodes, up to synchrotron radiation sources which provide the highest brilliance and density of x-rays. The range of precipitate sizes which can be investigated by this technique is of the order of $R = [0.5 \text{ nm}, 10 \text{ nm}]$ in usual experiments, and newly developed USAXS (Ultra Small Angles) enable to measure precipitate radii up to 100 nm.^[12] In most cases aluminum samples are studied close to the wavelength of CuK_α ($1.54 \text{ \AA}$, $\sim 7.8 \text{ keV}$), with an associated sample thickness of about $70\text{--}80 \mu\text{m}$.

A condition for using the SAXS method is of course that a high contrast in electronic density exists between the precipitates and the matrix, since the scattered intensity is proportional to the square of this $\Delta\rho$. This contrast is proportional to the difference in average atomic number, except if it is enhanced by taking an x-ray wavelength close to an

absorption edge of one of the elements (this case is referred to as *anomalous scattering*). Thus it is hopeless, for instance, to study by SAXS precipitation processes in an Al-Mg-Si alloy where the contrast between precipitates and matrix is almost zero. In this case, one can use Neutrons Scattering (SANS), since the scattering cross-section to neutrons is not proportional to the atomic number.^[13] SANS measurements can only be performed on scientific neutron nuclear reactors, which offer limited access, and are thus less straightforward than x-ray experiments. However, SANS measurements average on a much larger volume of the material, since neutrons can traverse more than 1 cm of aluminum.

SAXS and SANS share also one other advantage: they can be performed in-situ during complex thermal histories, if the sample is heated under the beam. Thus it is possible to obtain direct access to precipitation kinetics of isothermal or non-isothermal phase transformations.

The measurement of scattering provides a number of x-rays (or neutrons) per sec and per solid angle, as a function of the scattering vector $q = 4\pi \sin\theta/\lambda$, where θ is the scattering angle and λ the wavelength. This spectrum can be transformed easily in normalized intensity I (or scattering cross section $d\Sigma/d\Omega$), which will be used for subsequent analysis.^[11] One way to determine an average precipitate radius is then to consider Guinier's approximation, which states that in an intermediate range of scattering vectors the intensity is as follows:

$$I \propto \exp\left(-\frac{q^2 R_g^2}{3}\right)$$

R_g is the Guinier or gyration radius of the precipitates, and represents the mean square distance in the precipitate from the center of gravity, where the role of mass is played by the electrons. Under the initial calculation, this approximation was supposed to be true only for $q \cdot R_g \ll 1$. However, in practice it is best followed in the range $0.8 < q \cdot R_g < 2$.

One other useful result from the scattering spectrum is the large angle asymptotic behavior (so-called Porod behavior): at large angles the intensity becomes proportional to q^{-4} . If this is adjusted to the experimental behavior, the complete scattering behavior can be known until $+\infty$. Then the so-called invariant of the spectrum Q_0 (also called integrated intensity):

$$Q_0 = \int_0^\infty I(q) q^2 dq$$

can be calculated with precision. The integrated intensity yields several applications. The first is the calculation of an other average radius of the microstructure, the Porod radius, which is defined by:

$$R_p = \frac{3}{\pi(1-f_v)} \lim_{q \rightarrow \infty} \frac{Q_0}{I q^4} = 3 \frac{V}{S}$$

The Porod radius is actually proportional to the ratio between the volume of the precipitates and the surface of their interface with the matrix.

The integrated intensity can also be used for the determination of precipitate composition and volume fraction. This will be presented in “Volume Fraction and Chemistry” sections.

An ideal system for using Small-Angle X-ray Scattering is the 7000 series system, since the contrast between (Cu, Zn) atoms and (Al, Mg) atoms is very high. An example of a Guinier plot ($\ln(I)$ vs. q^2) is given in Fig. 3a. In situ measurements at different temperatures can provide a detailed description of the precipitation kinetics, including nucleation radii, growth and coarsening rates.^[14] Such results

Fig. 3 Guinier plot representing the logarithm of scattered intensity vs the square of the scattering vector. The linear part of the curve enables to calculate the Guinier radius of the microstructure (peak-aged 7050 alloy), which is 30 $\text{\AA}$; (b) Evolution of Guinier radius vs aging time at 160°C measured by in-situ SAXS in a ternary Al-Zn-Mg alloy and in the 7010 alloy (Al-Zn-Mg-Cu)^[14]

are shown in Fig. 3b. In some more complicated cases, where several precipitate families are present, the Guinier approximation is much less straightforward, because of the overlap of the scattering behaviors of the different families. In this case, the two distributions of precipitates can be visualized in a plot of the “integrated intensity”, i.e. $I \cdot q^2$ vs. q . In the example shown in Fig. 4, it was possible using Ultra-Small Angle X-ray Scattering to separate homogeneous precipitates and heterogeneous precipitates on grain and sub-grain boundaries.^[12] The respective precipitate sizes could be determined and the volume fraction of heterogeneous precipitates was found to represent approximately 10% of the total volume fraction.

Finally, the precipitate shape can *in principle* be determined by SAXS and SANS experiments.^[11] In practice this is not an easy task due to experimental limitations. However, if a geometry is known from TEM experiments for instance, its parameters (such as aspect ratio, parameters of a precipitate size distribution) can be determined in favorable conditions (high contrast, low background noise, good counting statistics, etc.); For instance, Donnadiou and co-workers were able to fit the parameters of a log-normal size distribution to a SANS spectrum of β'' precipitates found in the 6056 Al-Mg-Si-Cu alloy in the peak aging condition,^[5] as shown in Fig. 5. In this analysis, both the average diameter and the average height of the precipitates were determined, namely 2.5 nm and 8 nm.

Transmission Electron Microscopy

The alternative technique to study precipitate sizes is TEM. This technique is the exact complementary of SAXS and

Fig. 4 Ultra-small Angle X-ray Scattering measurements on 7040 alloy enable to separate in this $I \cdot q^2$ vs q plot two families of precipitates: intergranular coarse precipitates of radius approximately 700 $\text{\AA}$, and intragranular precipitates of radius 60 $\text{\AA}$. Note that in the case of a rapid quench intergranular precipitates are almost absent (Courtesy of D. Dumont, LTPCM, France)

Fig. 5 Small-Angle Neutron Scattering analysis on an Al-Mg-Si-Cu alloy in the T6 temper, (a) Fit of the experimental scattering spectrum supposing a log-normal distribution function of the precipitate sizes; (b) corresponding precipitate size distribution^[5]

SANS: it provides direct information on size, morphology and spatial distribution of precipitates, but is limited by poor statistics and the problem of a 2D projection of a 3D structure.

TEM is probably the only technique which can really provide information on the spatial distribution of precipitates. One can for instance characterize the precipitates-free zones which in some systems can exist close to grain boundaries (Fig. 6a) or around coarse quench-induced precipitates (Fig. 6b), or the nucleation mechanism of a coarse quench-induced precipitate on a previously existing dispersoid (Fig. 6c).^[15] Such microstructural features are extremely important to characterize as they control many mechanical properties such as the fracture behavior.^[16] The morphology can also be determined by TEM, such as the aspect ratio of plate-like η' precipitates in a 7108 alloy (Fig. 7). An average value of the aspect ratio can even be determined in some specific cases by the study of the diffraction patterns if the precipitates are very small, since the size of the precipitates in one given direction is inversely proportional to the

Fig. 6 Microstructures in the 7010 alloy (Al-Zn-Mg-Cu) as characterized by TEM; (a) Precipitate-Free Zone around a grain boundary; (b) Precipitate depleted zones around coarse quench induced precipitates after a slow quench from the solution treatment; (c) Quenched-induced precipitate nucleated on an Al_3Zr dispersoid (b and c from Ref. [15])

size of the diffraction spot in the orthogonal direction. This was used for instance by Donnadieu to determine the aspect ratio of precipitates in the 6056 alloy.^[5]

TEM micrographs can also be used to obtain directly the precipitate size distribution, using image analysis. This can be done on bright field images, however the non-uniform contrast of the precipitates and matrix make automatic detection of the precipitates impossible, and underlining the precipitate border by hand is necessary. This type of analysis can thus best be performed on dark field images, which provide high contrast between white precipitates and black matrix. However, the selection of one single diffraction spot for constructing the image means that many precipitates are not counted. Therefore it is necessary to know the different variants of the orientation between the precipitates and the matrix in order to be sure that the measured distribution is representative of the complete microstructure. The other issue concerns the shape of the precipitates. If the precipitates are spherical, the diameter

Fig. 7 η' precipitates in a Al-Zn-Mg alloy in the T6 condition. One can clearly see in this near-(111) zone axis the four crystallographic variants of the precipitates. The precipitates are platelets lying on the {111} planes of the matrix

measured on the pictures is the actual diameter of the precipitates, except if the sample thickness is of the order of the precipitate size: in this case, many precipitates are cut by the thinning process during sample preparation and thus only partly imaged. Some mathematical corrections exist to calculate the actual distribution from the measured one, provided of course that the sample thickness is known^[17] (see next section for the sample thickness measurements). Other simple cases may be easier to characterize: for instance, if the precipitates are rods oriented parallel to the [001] directions of the matrix, as is the case of β' in 6000 series, for instance, the analysis of a thin foil oriented as such will provide an exact measurement of the cross-section of these rods.

Volume Fraction

The evaluation of the volume fraction of precipitates is very important for the understanding of the mechanical properties of age-hardenable aluminum alloys. However, it is very seldom carried out because it is extremely delicate to perform. An independent quantitative determination of the volume fraction of small precipitates in one sample is a long and difficult work by itself. In this section we will describe which techniques may lead to a determination of volume fraction, and the degree of self-consistency of these methods.

Resistivity

The easiest method to determine precipitate volume fraction is also the most difficult to interpret. The principle of resistivity measurements during precipitation processes is to determine the loss of solute concentration in the matrix and convert this loss in volume fraction. This is achieved by the fact that precipitates do not scatter significantly electrons (except if they are too small, see below), contrarily to solute atoms. Therefore, as far as resistivity is concerned, a precipitation process is equivalent to a loss of solute from

the matrix. In order to interpret such measurements, a number of conditions have to be fulfilled:

- Mathiessen's law has to be verified, i.e. there should be a linear addition law between the solute contribution and the other contributions to resistivity (such as phonon scattering).
- the relationship between solute concentration and resistivity has to be known or calibrated.^[18]
- the composition of precipitates should be known, in order to relate the volume fraction to the amount of solute lost.
- One should be aware of the resistivity anomaly:^[19] when precipitates are small, they scatter more efficiently than solute atoms, and therefore the precipitation process induces an increase of resistivity instead of a decrease. This resistivity anomaly is strong up to sizes of about 2 nm in diameter. Therefore, in order to be completely aware, one should not attempt to measure precipitated volume fractions from resistivity below an average precipitate diameter of 5–10 nm.

This method has been successfully applied for instance by Godard in order to determine the evolution of precipitate volume fraction during continuous cooling from the solutionizing temperature in the 7010 alloy.^[20] Figure 8 shows the evolution of volume fraction for different cooling rates. These measurements can then be modeled in a Johnson-Mehl-Avrami framework. In this case, precipitates were presumed to be equilibrium $\text{Mg}-(\text{Zn}, \text{Cu})_2$ precipitates, and their size was relatively coarse because of their high nucleation temperature.

Small-Angle Scattering

The other relatively easy method for volume fraction measurements is Small-Angle Scattering (SAXS or SANS).^[21] For the principle of these experiments, see “X-Ray and Neutron Scattering” section. In a two-phase model (matrix of uniform concentration and all precipitates of the same composition), the integrated intensity Q_0 depends on the volume fraction in a simple manner:

$$Q_0 = 2\pi^2 f_v (1 - f_v) (\Delta\rho)^2$$

$\Delta\rho$ is the difference in electronic density between the precipitates and the matrix, and is expressed as:

$$\Delta\rho = \frac{Z_p}{\Omega_p} - \frac{Z_m}{\Omega_m}$$

where Z and Ω are the average atomic number and average atomic volume in the precipitate and the matrix, respectively.

The integrated intensity is first calculated in the measurement range $[q_0, q_1]$. If the precipitates are not too

Fig. 8 Study of precipitation processes during high temperature isothermal treatments using in-situ resistivity measurements, (a) evolution of resistivity during the heat treatments; (b) analysis in terms of normalized fraction of precipitates (Courtesy of D. Godard, LSG2M, France)

large (and therefore do not scatter to too small scattering angles), the integrated intensity from the $[0, q_0]$ part of the reciprocal space can be neglected. However, the large angle contribution $[q_b, \infty]$ is usually not negligible and has to be calculated. This can be simply achieved by fitting the asymptotic Porod behavior in the large angle section of the measured spectrum, and thus adjusting the constant A ;

$$I(q) \rightarrow \frac{A}{q^4}$$

Then the large-angle contribution to the integrated intensity is simply:

$$\Delta Q \int_1^\infty I(q) \cdot q^2 dq = \int_{q_l}^\infty \frac{A}{q^2} dq = \frac{A}{q_l}$$

Transmission Electron Microscopy

The volume fraction of precipitates can be estimated directly by means of Transmission Electron Microscopy.^[22] This technique has the advantage of being direct (no assumption is needed regarding the precipitates composition), but is very cumbersome and time consuming. The principle

is as follows: precipitates need to have a simple geometry (rods, spheres...) and to be aligned with respect to the electron beam. The contrast between the precipitates and matrix should be high, and therefore the dark field imaging mode is privileged. The number density and size of the 2-dimensions projection of the precipitates is measured on the photographs by image analysis. The total number density is then calculated by simple geometrical rules. For instance, in case of rods aligned along the $\langle 100 \rangle$ directions of the matrix, three variants are equivalent, and the total number density of precipitates is three times the one measured on a dark field micrograph taken with a single precipitate reflection. Finally, the sample thickness has to be measured. Several techniques are possible, but the two most suitable are the measurements by Convergent Beam Diffraction (CBED) and Electron Energy Loss Spectroscopy (EELS).

The EELS method is based on the measurement of the zero-loss peak intensity I_0 .^[23] It is related to the total intensity I_t by the relation $\log(I_t/I_0) = \exp(t/\lambda)$, where t is the sample thickness and λ is the mean free path of the electron in the material. Thus if the mean free path of the electron is known, the sample thickness can be known with good accuracy (about 10%) since the method relies

on the ratio between two intensities, and therefore does not depend on an absolute intensity measurement, λ can be computed from the experimental conditions provided that the material is appropriately described by the free-electron approximation.

However, the CBD method appears to be both more precise and more easy to use than the EELS method.^[22] It is applicable to most TEM samples, and fails only with extremely thin samples (<10 nm), heavily distorted structures (large strain deformations) or very absorbing elements (e.g. gold). The method and range of applications can be found in.^[24] It consists of making a CBD pattern under two-beam conditions and in measuring the positions of the fringes inside the diffraction disc, which leads for each fringe to the related deviation s to Bragg angle (Fig. 9). According to the two-beam dynamical theory,^[25] the distribution of diffracted intensity depends

on the deviation s , the extinction distance ξ_g and the local thickness t . The white and black fringes correspond to the intensity extrema. Therefore, it is possible to derive the local sample thickness from the fringe positions. The range of measurable thickness depends on the extinction distance and on the absorption coefficients. According to Allen,^[24] measurements are possible in aluminum between 22 and 790 nm under two-beam conditions with a diffraction vector $g(220)$.

Finally, corrections have to be made in order to take into account the fact that some precipitates are cut by the sample surface. Again, the correction depends on the geometry of the precipitates. In case of spheres, the apparent diameter of the precipitates will be changed by this artifact. Mathematical corrections such as the Schwartz-Saltikov method^[17] are available to get the actual precipitate size distribution and number density. In the case of rods perpendicular to the sample surface and parallel to the electron beam, the correction will depend on their height as compared to the thickness of the sample. If the experimental height distribution is known (for instance by the analysis of the diffuse scattering in the diffraction patterns), as well as the sample thickness, the actual distribution and number density of precipitates can also be calculated.

Tomographie Atom Probe

Perhaps the most direct method of all, the newly developed Tomographie Atom Probe (TAP) enables the direct reconstruction in 3 dimensions of the sample volume, atom by atom.^[26] Thus it enables the full determination of the microstructure, including the precipitate size, composition and volume fraction, as well as the solute content of the matrix, for instance (see Fig. 10). Of course the disadvantage is a very poor statistics as compared to other experimental techniques, since only a few 100,000 atoms can be analyzed per needle.

This technique can also lead to some artifacts due to local magnification effects, and therefore the measurements obtained by this technique should be checked with other experimental techniques such as the ones exposed above.

Chemistry

Determining the chemistry of fine scale precipitates is a rather complicated task. First, fine scale precipitates in aluminum alloys are usually not of the same crystallographic nature as the stable phase predicted by the phase diagrams. There is therefore no reason for which their composition should be similar to the bulk composition of the intermetallic phases. Moreover, fine precipitates are usually associated with a strain field, which can substantially change their equilibrium concentration in the various solutes.

Knowing the precipitate composition is however very important. The balance between the various solutes (in the frequent case of a multi-constituent alloy) can determine

Fig. 9 (a) Dark Field Electron Micrograph of 6056 aluminum alloy ([100] zone axis), showing the presence of β'' precipitates in the shape of rods. The volume fraction of these precipitates could be determined in this sample by analyzing the sample thickness using a convergent beam diffraction image of a (220) spot (b). The thickness of the sample can be determined from the spacing between the fringes in the diffracted spot (Courtesy of P. Donnadiou, LTPCM, France)

Fig. 10 Determination of the Zn composition of η precipitates in an Al-Zn-Mg alloy by SAXS measurements: Given some hypothesis concerning the Zn concentration in solid solution (measured by Tomographie Atom Probe) and the composition in aluminum of the precipitates, the intersection of the two curves gives the Zn concentration of the precipitates and the precipitated volume fraction. TAP measurements showed very good agreement with the result

the evolution of the precipitation driving force during the aging process. The total content of solute in the precipitate (or in other words the aluminum content in the precipitates) determines in turn the volume fraction attainable for a given amount of solute and can have substantial consequences on the resulting mechanical properties of the material.

Several methods are available for measuring the composition of nanoscale precipitates. However, even though these methods are probably relatively reliable for the determination of the relative balance between the different elements other than aluminum (for instance, the ratio between Si, Mg and Cu in a 6000 series aluminum alloy), the aluminum content of the precipitates cannot be measured with certainty in the present state of the art.

Transmission Electron Microscopy

A first method for analysis of precipitates composition is the use of TEM. However, dealing with nanometer sized precipitates means that the beam has to be focused on a similar scale. This is best achieved in STEMs (Scanning Transmission Electron Microscopes), which can provide when equipped with a Field Emission Gun probe sizes down to 1 nm. Two methods can be then used to measure the precipitate composition: Energy Dispersive X-Ray Spectroscopy (EDXS),^[27,28] or Electron Energy Loss Spectroscopy (EELS).^[29,30] The main problem for both methods is to isolate the precipitate from the matrix. Ideally, the sample should be prepared in form of carbon replica so that there is no interaction with the aluminum of the matrix

in the measurement. In practice, this is often impossible for very small precipitates and the main result of the measurement will be the ratio between the different solutes inside the precipitates.

EDX analysis can be achieved for all elements except the lightest elements (when the detector is equipped with a beryllium window lighter than Na). With EDX the spatial resolution of the analysis is about 2 nm in diameter, due to the beam broadening across the sample. With an acceleration voltage of 100 kV, the sample should be thinner than 100 nm in order to get a reasonable signal-to-noise ratio. Quantitative analysis is possible provided that more than 1 at% of the element to measure is present. Of course quantitative analysis are best performed if some standards (e.g. pure materials, phases of known composition) are measured in parallel. If not, the composition can be calculated from EDX spectra using appropriate softwares, but only if the *K* or *L* edges of the element can be recorded. An example of the type of study which can be carried out with STEM is shown in Fig. 11. The composition across a Precipitate-Free zone is measured by EDX in an Al-Zn-Mg-Cu alloy. The solute depletion of the PFZ is clearly identified on the calculated Zn profile, and also an increase in Zn concentration is observed on the grain boundary, due to the presence of a grain boundary precipitate.

Fig. 11 (a) TEM micrograph showing a Precipitate-Free Zone around a grain boundary in an Al-Zn-Mg-Cu alloy; (b) Zn profile of across this Precipitate Free Zone showing the solute depletion in the PFZ and the sole enrichment close to the grain boundary precipitate (Courtesy of D. Solas and M.C. Cheynet, LTPCM, France)

EELS analysis enables the detection of all elements, but is particularly sensitive to light elements. In this mode spatial resolution of the analysis is better than in EDXS mode and can be as low as 1 nm. When the sample is free of contamination and is thinner than 50 nm, quantification can be performed with a good accuracy for all light elements as well as for elements up to the transition series. For heavier elements quantification becomes impossible without standards. Thus EELS and EDXS are complementary techniques that can be used to solve micro and nano-analytical problems. Figure 12 shows an example of the use of the combination of these techniques to determine the composition of very small oxide particles MgAl_2O_4 at the interface of SiC particles in a SiC-reinforced Al-Mg alloy. Moreover, in this case the composition profiles of the various elements could be measured across the interface from EDX measurements.

Small Angle X-ray Scattering

Small-Angle X-ray Scattering can be used for determining some characteristics of the composition of precipitates.

However, a complete determination is impossible, since a high density of dilute precipitates will give the same SAXS signal as a low density of concentrated precipitates, as discussed in “Small-Angle Scattering” section. Actually, if one is able to determine one parameter of the microstructure, the others can be fully determined by SAXS measurements. For instance, the determination of the solute concentration left in the matrix enables the calculation of the solute concentration in the precipitates and of the volume fraction, at least in a binary alloy or a pseudo-binary alloy, as shown in Fig. 10.

In complicated systems including several elements, information about the relative fraction of elements can be obtained from anomalous SAXS (so-called ASAXS). This technique consists in measuring the SAXS spectra for various wavelengths of the x-rays, approaching the absorption edge for one of the elements in the alloy.

We have seen above that intensity of the scattered signal is proportional $|\Delta\rho|^2$, where $\Delta\rho$ is the difference in electronic density between the matrix and precipitates. The electronic density writes $\rho = f/\Omega$, where f is the scattering factor to x-rays at the wavelength used in the experiment

Fig. 12 Analysis of a sample of Al-Mg alloy reinforced with SiC particles by STEM using EDX and EELS detection, (a) TEM micrograph showing the interface between the Al matrix and the SiC particle; (b) Calculated concentration profiles from EDX measurements in the different elements across the interface; (c) EELS spectrum on the very small particles at the SiC/Mg₂Si interface showing the presence of the MgAl_2O_4 phase (Courtesy of M.C. Cheynet and J.J. Blandin, LTPCM and GPM2, France)

and Ω is the atomic volume. Far away from an absorption edge, f is almost equal to the atomic number Z . However, when approaching an edge, the scattering factor writes:

$$f = f_0 + f' + if''$$

Where f' accounts for the absorption and f'' accounts for the fluorescence of x-rays (z is the imaginary number). The values of f' and f'' are tabulated in the Cromer-Liberman formalism,^[31] which can be used if the energy shift to the edge $\Delta E/E_e$ is larger than the energy dispersion of the beam used.

Thus one can monitor precisely the contrast between one atomic specie and the others in a given microstructure. This enables to obtain very useful information on the presence of this atom in a given family of precipitates. This was achieved for instance on a Al-Li-Cu-Mg alloy, where the authors were able to separate the contributions of the Al_3Li (δ') precipitation and the GPB zones containing (Al, Cu, Mg) by studying the copper edge (Fig. 13).^[32] In an other study, the same authors were able to show that the composition in copper of η' precipitates in an Al-Zn-Mg-Cu alloy was very small, ranging from 1 to 7 at% depending on the state of aging.^[33]

Of course, using this technique is quite delicate, since one needs to be able to control and change precisely the wavelength of x-rays near a given value which is the edge of interest. Thus the x-ray experiment should be equipped with a good monochromator. This is best achieved with synchrotron radiation sources, which provide a high flux of x-rays. Finally, one should note that this technique is not applicable to any elements: it works very well for elements such as Cu, Zn, Fe, but is almost impossible to carry out on Mg or Si: at the edge energies for these elements, the x-rays do not traverse more than a few nanometers of aluminum. Thus it is not reasonable to use ASAXS for characterizing

Fig. 13 Anomalous x-ray scattering performed on an Al-Li-Cu-Mg alloy. The spectrum, representative of GPB zones, is clearly dependent on the energy of x-rays when approaching the CuK α edge. This enables to characterize the presence of copper in the precipitates (From Ref. 32)

an Al-Mg-Si alloy, for instance: in this case, one should use neutrons scattering.

Tomographie Atom Probe

The ideal method for determining the precipitates composition if the recently developed Tomographie Atom Probe. This apparatus enables the full characterization of the microstructure with atom-scale precision, and thus can provide the composition of individual precipitates.^[26] This powerful technique is of course extremely difficult to carry out, and can at this date only be performed in a few places.

TAP measurements provide an individual precipitate composition. This means that an idea of the variability of this composition from one precipitate to an other can be obtained, whereas this is very difficult to obtain by other means. In turn, it is delicate to obtain a good statistics with this technique: at best, a few dozens of precipitates can be measured for a given state in a reasonable time (see Fig. 14).

The main problem with the Tomographie Atom Probe is its uniqueness: indeed, it is the only technique which can provide such local results, and needs to be checked with other more indirect methods before one can be sure of its results. Measurements have been carried out on a 7000 series aluminum alloy designed for favoring the precipitation of the T' phase.^[34] For precipitates of an average diameter of 9 nm, the composition of this phase was found by TAP to be 38% Mg, 37% Al and 25% Zn. This composition is very close to the equilibrium concentration of the T phase ($\text{Mg}_{32}(\text{Al}, \text{Zn})_{49}$), which contains 39.5% Mg. This results suggests that the precision of this technique is very good even for precipitates having a small size.

However, an other study on a ternary Al-Zn-Mg, this time promoting the precipitation of the η' and η phase, has lead to less clear-cut results. First, the measured compositions in η' were found to be very far from the equilibrium composition of η (MgZn_2): more than 50% of aluminum was found in the early stages of aging (precipitates 3 nm in diameter).^[35] Secondly, a parallel study in Small Angle X-Ray Scattering was in disagreement with the TAP

Fig. 14 3D reconstruction of a Al-Zn-Mg needle analyzed with the Tomographie Atom Probe. Black dots represent solute atoms, precipitates are clearly identified and can then be analyzed in terms of size, chemistry and volume fraction (Courtesy of A. Bigot, University of Rouen, France)

results in these early stages, whereas the two studies were consistent in later stages where precipitates were larger and did not contain more than 15% Al.

The possible artifacts of this method are numerous, perhaps the most relevant in this case is the local magnification effect: at the end of a TAP needle, the radius of curvature of a precipitate can be substantially different than the radius of curvature of the matrix, due to capillary effects. In this case, there can be some mixing between the composition measurements in the matrix and in the precipitates.

In summary, Tomographie Atom Probe results for the determination of precipitates composition are extremely useful but should still be checked with other experimental techniques when the size of the measured objects is very small (less than 10 nm in diameter). However, although there is still a doubt about the high aluminum concentrations which are sometimes found in TAP studies, the measurement of the ratios between various solute species is thought to be very reliable.

Precipitation Sequence

Precipitation hardening aluminum alloys are characterized by very complex precipitation sequences, which include several metastable phases. During usual thermomechanical sequences, several of these phases appear sequentially. The way these phases nucleate in the presence of the precedent phase is complicated: in Al-Zn-Mg alloys, for instance, the presence of GP zones promotes the nucleation of η' , whereas in Al-Mg-Si alloys, the presence of GP zones or solute clusters inhibits the precipitation of β'' . The privileged technique to study these precipitation sequences is Differential Scanning Calorimetry, which measures the heat exchange between a sample and its environment during a thermal sequence.

DSC measurements can be used in several ways, which will be detailed below. However, one should keep in mind that the outcome of it can usually only be analyzed in a qualitative manner, and the validity of the interpretations should be checked carefully with other experimental techniques (e.g. the type of phases present at one stage of the thermal sequence can be checked by Transmission Electron Microscopy).

DSC can first be used as a probe of the microstructure present at one stage of a thermomechanical sequence. In this case, the thermal sequence will be a fast heating ramp ($>50^\circ\text{C}/\text{min}$), so that no phase transformation can occur during the heating ramp except the dissolution of the phases present at the beginning of the test. The type of phases present at the beginning can be then analyzed from the dissolution temperature. This method is illustrated in Fig. 15 in 6 Al-Zn-Mg alloys containing 5 wt% Zn, 2 wt% Mg and increasing amounts of copper ranging from 0% to 1.6 wt%.^[36] One dissolution peak occurs at constant temperature for all alloys and is interpreted as corresponding to Al-Zn-Mg GP zones. A second dissolution peak occurs

Fig. 15 DSC thermograms for Al-Zn-Mg alloys containing an increasing amount of copper, performed after a quench and 40 days at room temperature. The heating rate is $80^\circ\text{C}/\text{min}$. One can see clearly the transition from one low-temperature dissolution peak for alloys 1–5 to two dissolution peaks for alloy 6 (From Ref. 36)

at higher temperature in the high copper containing alloys and corresponds to a second family of GP zones containing copper.

A second way of using DSC is to simulate the heat treatment which is used for obtaining the desired precipitation structure. In this case, one can vary the experimental conditions of the initial conditions and of the heating ramp to observe the induced changes in phase transformations. For this purpose, slow heating ramps need to be used, since the precipitation treatments in aluminum alloys are usually carried out with slow ramps. Depending on the equipment used, reasonable data can be obtained with heating ramps down to $0.3\text{--}1^\circ\text{C}/\text{min}$. Of course, ideally one would like to carry out isothermal treatments in the DSC (even possibly after a heating ramp), in order to simulate perfectly the actual thermal history of the material studied. However, extremely sensitive equipment need to be used in order to do so, since after a few hours of heat treatment, the heat exchange signal between the sample and its environment becomes ridiculously small.

Such equipment exists, and has been used to study very low-signal transformations, such as grain growth. However it is not very widely spread such as conventional DSC. An example of such an experimental method is shown in Fig. 16, where the thermograms of an Al-Zn-Mg alloys are represented.^[14] The heating ramp is varied from 0.5°C/min, C/min, representing the industrial heat treatment, and 5°C/min, in order to characterize the effect of the heating ramp on phase transformations. One can observe that the low-temperature dissolution peak of GP zones is much more extensive if the heating ramp is faster, resulting in a less well-defined η' precipitation peak at higher temperature. Thus this experiment enables to state the detrimental effect of increasing the heating ramp on nucleation of the hardening η' phase.

Finally, DSC can be used to study the kinetics of phase transformations, and notably to determine activation energies for transformations. However, in aluminum alloys this is often delicate, since a reasonable estimate of such quantities can only be obtained in the case of an isolated DSC peak, whereas in most practical cases DSC scans show interrelated peaks, exotherms following endotherms, etc. Moreover, such studies should be carried out on transformations which nature do not depend on the heating ramp: this is rarely true in aluminum alloys! One example of this methodology is shown in Fig. 17. Figure 17a shows DSC thermograms performed on alloy 2219-T31 at rates between 1 and 20 K/min.^[37] These thermograms show two reasonably separated peaks, one corresponding to dissolution of GP zones, and the second to precipitation of the θ' phase. Integration of the second peak with temperature enables to plot the evolution of transformed fraction α with temperature for the different heating rates. The starting point of the analysis is a general relationship between the transformed fraction α , the reaction rate coefficient $k(T)$ and time t :

Fig. 16 DSC thermograms performed on an Al-Zn-Mg alloy after quench and 3 days at room temperature. The faster heating ramp increases the magnitude of the low-temperature GP zones dissolution peak (A), resulting in a less well-defined precipitation peak of the hardening phase η' (B) (From Ref. 14)

Fig. 17 (a) DSC thermograms of alloy 2219-T31 as a function of heating rate, (b) Interpretation of the transformed fraction in terms of Avrami formalism, resulting in an activation energy of 117 kJ/mol and $n = 1.1$ (From Ref. 37)

$$f(\alpha) = k(T)t$$

Assuming that the rate coefficient follows an Arrhenius equation, and that the heating rate $\phi = dT/dt$ is constant, one obtains:

$$f(\alpha) = \frac{AE}{R\phi} p(x)$$

where A is the pre-exponential term in the Arrhenius equation, E is the activation energy, R the universal gas constant and

$$p(x) = \int_0^{\infty} \frac{\exp(-x)}{x^2} dx$$

$f(\alpha)$ is finally often fitted to an Avrami law:

$$f(\alpha) = [-1n(-\alpha)]^{1/n}$$

Such a fit for the precipitation of θ' is shown in Fig. 17b, and results in the following value for the parameters: $E = 117 \text{ kJ/mol}$, $A = 3.10^9 \text{ s}^{-1}$ and $n = 1.1$. The activation energy is close to the one of copper diffusion in aluminum, and the value $n = 1.1$ indicates some sort of growth-controlled reaction.

Other Problems

A number of other characteristics of precipitates often need to be characterized; however, it is not the purpose of this chapter to be completely exhaustive, so we will only give a brief survey of how less widespread precipitate characteristics can be characterized.

- Coherency strains around coherent or semi-coherent precipitate can be analyzed by image analysis of TEM images taken in well controlled imaging conditions.
- The study of the interface between the precipitates and the matrix is best studied by High Resolution Electron Microscopy (HREM).
- The internal chemical order in the precipitates can be studied by some x-ray techniques such as EXAFS (Extended X-ray Absorption Fine Structure) and XANES (X-ray Absorption Near Edge Spectroscopy), which both study the local dependence of the transmission to x-rays of a sample as a function of wavelength near an absorption edge.

CHARACTERIZATION OF SECOND PHASE PARTICLES

The characterization of large second-phase particles in aluminum alloys needs to meet a number of requirements, which are dictated by the aspects of the process and properties which may be controlled by their presence. For instance, second phase particles play an important role in the occurrence of recrystallization and on the resulting texture, and determine significantly the resistance of the material to fatigue by promoting the nucleation of microcracks in the material.

First, the type of phase needs to be determined (crystallography and composition) for these particles, in order to control the temperature domain where they may appear in the micro structure. Another important parameter is obviously the volume fraction of the various phases, and their size. However, more important is their geometry, since a number of them (e.g. $\text{Al}_7\text{Cu}_2\text{Fe}$) have very complicated shapes. It is well known that the aspect ratio of hard particles can influence very significantly their role on the microstructure formation. Finally, one other characteristic of these phases is that they are not distributed homogeneously in space, and it is important to characterize both their location as compared to other defects (and particularly grain and sub-grain boundaries), as well as their degree of clustering.

Phase Type, Crystallographic Structure, Composition

Optical Microscopy

Optical microscopy offers an easy and efficient way of characterizing the type of precipitates. Notably, in well known alloy systems, the various phases can be chemically etched to different colors, and thus identified. Figure 18 shows for instance the use of the Keller etch to reveal the intermetallic phase Mg_2Si in an Al-Mg-Mn alloy.

Scanning Electron Microscopy

The SEM is probably the most efficient way to characterize the type of second phase particles in classical materials where the phases have been identified in terms of composition and crystallographic structure. The sample preparation is easy and fast, and the apparatus is well adapted to the size of the particles (a few microns).

The type of second-phase particle is determined from its composition through an x-ray analysis (Energy Dispersive X-ray detector, or Wavelength Dispersive X-ray detector for better resolution in energy). The volume of the material which participates to the emission of x-rays under the electron beam is about $1 \mu\text{m}$ in diameter for aluminum under standard operating conditions (20 kV). Thus it is not reasonable to characterize quantitatively the composition of second phase particles which smallest size is smaller than $1 \mu\text{m}$.

For particles which are large enough, truly quantitative analysis of the composition can only be obtained by comparison of the x-ray signal with spectra of pure materials analyzed under the same experimental conditions. In this case, good precision on the compositions can be obtained ($\pm 1\%$ in absolute values).

However, a qualitative analysis is often sufficient to enable the determination of the phase type, in systems where these are well known and characterized. For

Fig. 18 Optical micrograph of an Al-Mg-Mn alloy (5383) after Keller etching (HNO_3 , HCl , HF , H_2O). The Mg_2Si phase appears in gray and the micro-porosity in black (Courtesy of S. Péron, LTPCM, France)

Fig. 19 Intermetallic particles in a 7050 alloy. White particles consist in $\text{Al}_7\text{Cu}_2\text{Fe}$ and AlCu_2Mg particles; black particles in Mg_2Si particles (Courtesy of D. Dumont, LTPCM, France)

instance, if one finds Fe, Cu and Al in a second phase particle in a 7000 series aluminum alloy, as shown in Fig. 19, the particle is definitely $\text{Al}_7\text{Cu}_2\text{Fe}$. In a 3000 series alloy, a qualitative analysis is often sufficient to determine if a particle is Al_6Mn or AlMn . Qualitative analysis in the SEM is simply carried out by fitting the measured spectrum with peaks calculated from standards stored in the computer. One point which is important in a qualitative chemical analysis is that the computer system will always complete the composition to 100%, even if the user forgets an important element in the analysis. Therefore, this method is best to measure roughly the ratio between the compositions in different elements, and not for self-consistent absolute measurements.

The SEM can also be used in x-ray mapping mode in order to make a cartography of the different atomic species present in the material. For this purpose some areas of the x-ray spectrum, corresponding to the different species, are recorded for each point of the map. Figure 20 shows an example of such maps for Al, Si, Cu and Fe in a 7000 series aluminum alloy. One can clearly distinguish $\text{Al}_7\text{Cu}_2\text{Fe}$ and Mg_2Si phases. This result was obtained with a Field-Emission Gun SEM, which provides much higher resolution than a conventional SEM.

Transmission Electron Microscopy

The use of Transmission Electron Microscopy becomes necessary in some specific cases: when precipitates are too small to be detected by the SEM (e.g. dispersoids), when the crystallographic structure of the precipitate is important to know, or when one wants to characterize quantitatively the composition of sub-micron sized particles.

The crystallographic nature of the precipitates can be inferred from diffraction patterns. However, a good sample preparation is necessary for this purpose, since second phase particles, of a different chemical nature than the matrix, are often not thinned as efficiently as the matrix, and therefore are very thick and difficult to observe in the microscope.

The chemistry of large particles is very straightforward to obtain in a TEM equipped with an EDX detector. For

Fig. 20 Chemical characterization of a second phase particle in AA7050 alloy. The backscattered electrons image shows that the particle is composed of two phases. The various maps of composition show that the central part of the particle contains Cu and Fe (composition: $\text{Al}_7\text{Cu}_2\text{Fe}$). The particle at the periphery contains Si and is Mg_2Si (Courtesy of D. Dumont, LTPCM, France. Images obtained with the help of J.-L. Pastol, CECM, France)

really quantitative measurements, however, two conditions need to be fulfilled: the particle needs to be separated from the matrix, i.e. the electron beam should not cross any matrix but only the precipitate, and the intensities of the x-ray emission of the different atomic species have to be calibrated with reference samples.

Geometrical Information: Experiments

Second phase particles in aluminum alloys have some specific geometrical characteristics which make their analysis particularly difficult to formalize. They are often non-symmetrical and complicated in shape with a high surface-to-volume ratio, they are not evenly distributed in space, they are clustered, and their volume fraction is very small.

Several experimental methods exist which can provide many data with all this information. However, the most difficult is sometimes to find the relevant mathematical analysis which can provide a simple parameter which is well related to a given property (e.g. the degree of clustering of particles and the fatigue life).

Optical Microscopy

Optical microscopy offers good potential for the observation of large areas of the material. One useful technique is to observe on the same sample several features of the microstructure by applying sequentially different etching procedures. One can then determine if the particles are lying mostly on the grain or subgrain boundaries, for instance.

The main problem with optical microscopy is the difficulty to carry out quantitative measurements by direct image analysis. This is largely due to the non-uniformity of the light in the observation area of the microscopy, which results in non-uniform light on the photographs.

Scanning Electron Microscopy

The most useful technique is probably the SEM. It offers good resolution, uniform light and digital ready-to-analyze data.

The usual observation mode is of course back-scattered electrons. They offer high contrast between the particles and matrix if they have a significantly different atomic weight. Moreover, in this mode the contrast is extremely uniform both for the matrix and the particles (if their composition is constant, of course), and therefore it is very easy to perform automatic image analysis. Figure 19 shows for instance intermetallic particles of $\text{Al}_7\text{Cu}_2\text{Fe}$ in a 7000 series alloy.

Recently, the development of Field Emission Guns for SEMs has increased drastically the resolution of this technique. It is now possible to image in Back-Scattered mode precipitates smaller than 100 nm.

From 2D to 3D: Reconstruction Techniques

One important problem in utilizing the precedent experimental techniques to characterize second phase particles is the fact that they provide only a 2-dimensions section of the microstructure. One good example of the mistakes that can be done is the microstructure of an eutectic Sr-modified Al-Si alloy. This alloy consists in a network of fibrous eutectic, as shown in Fig. 21b, where the aluminum matrix has been etched away. However, an observation of the polished surface in the SEM shows a microstructure which looks very similar to a distribution of globules (Fig. 21a).

Through this example, we can see that due to the nature of second phase particles, which have a complicated, non-uniform, high aspect ratio geometry, important mistakes can be made in the characterization of precipitates if one keeps the analysis to 2 dimensions.

A method for obtaining data on the microstructure from 2 dimensions sections consists in taking sequential images at various depths, the sample being polished down to the desired thickness between each photograph. Software can

Fig. 21 Eutectic structure in a Sr-modified Al-Si alloy of eutectic composition, (a) The backscattered electrons image of the polished surface gives no indication of a continuous fibrous structure of the Si phase; (b) this fibrous structure is revealed by deep etching of the aluminum phase and subsequent observation in the SEM (Courtesy of G. Guiglionda, University of British Columbia, Canada)

then be used to reconstruct the volume from the sequence of images.

This technique is obviously very cumbersome, and offers discontinuous reconstruction of the volume of the material. Therefore it is used only relatively rarely, when 3D information is absolutely needed.

True 3D: the High Resolution X-ray Tomography

Recently, the development of high brilliance x-ray sources such as the European Synchrotron Radiation Facility (ESRF) in Grenoble, as well as the development of powerful computers, has led to a new characterization technique of the 3D structure of bulk materials. High resolution computed tomography is a non-destructive technique that can be used to obtain images of the interior of micro-heterogeneous materials such as metal matrix composites or alloys containing micron-size heterogeneous particles. The principle is described briefly as follows (more details can be found in the work of Kak and Slaney.^[38]). A beam of x-rays fired at a rotating sample produces a 2-dimensional projection of the sample which is recorded on a charge coupled device (CCD) detector set behind the sample. In classical tomography (attenuation tomography), the contrast on 2-dimensional projections arises from the attenuation coefficients of each phase present in the material. Once recorded, the different 2-dimensional projections are combined mathematically through a filtered back projection software to re-create a 3-dimensional map of the distribution of attenuation coefficients in the material, $\mu(x, y, z)$. The final result is a numerical 3-dimensional grey level image divided into volume elements called

voxels. When the attenuation coefficients of the phases in the material are very similar, (Al/SiC, for example), the phase contrast tomography obtained with coherent synchrotron x-ray sources provides reconstructed images with improved contrast. The experimental set up is similar to the attenuation mode, only the detector is located further away from the object at a distance which depends on the x-ray energy and on the size of the microheterogeneity to be imaged. Diffraction occurs whenever the x-ray beam encounters an interface. The deflected and non-deflected waves interfere giving Fraunhofer and Fresnel fringes and an “edge contrast” outline image.^[39] A classical algorithm is then used to computationally extract a high quality image from the 2-dimensional projections. An example of such a reconstruction is shown in Fig. 22, in the case of secondary phase particles (mainly Fe-containing phases) present in an Al-Zn-Mg-Cu alloy. From such a 3D reconstruction, it is now possible to compute the detailed shape of the particles and to determine the degree of clustering in the various directions of the sample.

Geometrical Information: Analysis

Standard Output of Image Analysis

When image analysis is carried out with a standard software, the output is the characteristics of each single particle detected, and then the statistical analysis of the complete distribution. Some useful parameters can be detailed as follows:

- the Ferret diameter is the diameter of a disk of equivalent area.
- the elongation is the aspect ratio (the ratio between the major axis size and the minor axis size).
- the perimeter which can describe the complexity of the shape of the particle.

For a more detailed description of the possibilities one can refer to the free image analysis software ImageTool developed by the University of Texas Health Science Center (<http://www.ddsdx.uthscsa.edu/dig/download.html>).

The area fraction is simply calculated as the ratio between the number of pixels inside the detected particles divided by the total number of pixels.

These parameters enable the determination of average values for the particles geometry (average size, elongation, interface with the matrix). An interesting analysis is for instance the degree of correlation between the orientation of the main axis of the particle and the geometry of the sample in a rolled material, as shown in Fig. 23. This analysis shows very clearly that elongated particles can only survive if they are parallel to the rolling plane. If they have a large angle with the rolling plane at the beginning of the rolling process, they are broken down in smaller, less elongated particles. This anisotropy of the particles shapes can

Fig. 22 Characterization of the 3-D structure of second phase particles in a 7000 alloy using high resolution x-ray tomography. Second phase particles appear in red and porosity appears in green (Courtesy of E. Maire and J.-Y. Buffiere, GEMPPM, France, and C. Sigli, Pechiney - CRV, France. Image obtained with the help of J. Baruchel, P. Cloetens, and W. Ludwig at the ID19 beamline of ESRF, France)

have important consequences on crack initiation in fatigue, for instance.

However these parameters do not give any information on the distribution of the particles, which can also be an important parameter for the property control.

Voronoi Cell Analysis

A useful method for characterizing the spatial distribution of second-phase particles is to construct Voronoi cells around the center of gravity of each particle. This is achieved by constructing the median between each two neighboring particles. The Voronoi cell around one particle is then given by the intersection of all the medians which are nearest to this particle, as shown in Fig. 24 for intermetallic particles in a 7000 series aluminum alloy. The degree of clustering of the particles can be detected by considering the ratio between the standard deviation and the average value of the surface of the Voronoi cells. A random distribution of particles leads to a ratio of 0.5, and the degree of clustering increases when this ratio increases.

For instance, the microstructure represented in Fig. 24a is highly clustered with a ratio of 1.4, whereas the structure in Fig. 24b is moderately clustered with a ratio of 0.7.

Abstract

Anisotropy is a key feature of the plastic behavior of aluminum alloy sheets. Significant research efforts have been dedicated during the past few decades to characterize and model this behavior. Advanced anisotropic yield criteria are available today in the scientific literature. This article reviews the most important yield criteria, in historical order, with an emphasis on the models particularly adapted to aluminum alloys. Along with the mathematical description, illustrations of their performance are provided together with the parameter identification procedure and the required input data. The mechanical parameters that describe plastic anisotropy are also summarized. The relevance of the available models for practical applications is analyzed, and guidance is provided for the selection and aware use of these yield criteria in engineering.

Keywords: Aluminum; Anisotropy; Modeling; Plasticity; Sheet metal; Yield criteria.

INTRODUCTION

The yield criterion is a key concept in metal plasticity. The *yield surface* designates the locus, in stress space, of the stress states leading to the onset of plastic flow. For a given material state, all the stress states inside the yield surface are elastic, whereas the stress states outside it are not accessible.

In terms of modeling, this surface is described by a *yield function*—a stress-like scalar function f of the stress tensor components σ :

$$f(\sigma) \leq Y. \quad (1)$$

The inequality in Eq. 1 defines the *yield criterion*, relating the yield function to a material-dependent limit value (e.g., the material's plastic flow stress under a particular loading).

The yield criterion concept has two powerful consequences. First, the 3D plastic yielding behavior can be modeled based on a single experimental value, Y . Second, the direction of the plastic strain rate tensor is defined by the gradient of the yield function:

$$\frac{\dot{\epsilon}^p}{\|\dot{\epsilon}^p\|} = \frac{\partial f}{\partial \sigma}. \quad (2)$$

These underlying properties reduce the remaining plastic modeling to apparently scalar models, like the flow curve. However, the entire relevance of the overall models relies on the accuracy of the yield criterion.

The choice of the yield function in Eq. 1 is not uniquely defined, since some arbitrary mathematical manipulation can

be applied to both f and Y , and the criterion remains valid (as well as Eq. 2). Most often, such manipulations serve to transform the left-hand side of Eq. 1 into a stress-like quantity, the *equivalent stress*, whereas the right-hand side becomes the yield stress corresponding to a particular loading. This loading can be arbitrarily selected as shear, balanced biaxial, and so on, but the most usual is the tensile loading in the rolling direction (RD). In this case, the yield criterion relates the equivalent stress $\bar{\sigma}$ to the tensile yield stress σ_0 in the RD:

$$\bar{\sigma}(\sigma) \leq \sigma_0. \quad (3)$$

This article gives an overview of the models available in this category. The main definitions and properties related to plastic anisotropy are presented in “Anisotropy Of Cold-Rolled Sheet Metals” section. Sections “Classical Yield Criteria for Anisotropic Sheet Metals” and “Advanced Anisotropic Yield Criteria” review the most relevant yield criteria for aluminum alloys. The application of yield criteria in industrial practice is tackled in “Practical Application of Yield Criteria for Process Simulation” section. The conclusions in “Conclusions” section contain recommendations for choice and perspectives.

ANISOTROPY OF COLD-ROLLED SHEET METALS

Due to the characteristics of the cold rolling process, sheet metals exhibit a significant anisotropy.^[1] In fact, the rolling

Fig. 1 Orthotropy axes of cold-rolled sheet metals: RD (axis 1), TD (axis 2), and ND (axis 3)

process induces a particular anisotropy characterized by the symmetry of the mechanical properties with respect to three orthogonal planes. Such a mechanical behavior is called orthotropy. The intersection lines of the symmetry planes are the orthotropy axes. In the case of cold-rolled sheet metals, these axes are oriented as follows (Fig. 1): RD (axis 1), transverse direction (TD—axis 2), and normal direction (ND—axis 3).

Quantitative Description of Plastic Anisotropy in Uniaxial Traction

The quantities used to describe the plastic anisotropy of cold-rolled sheet metals in the uniaxial tension regime are the (uniaxial) yield stress and the Lankford coefficient. Both quantities are determined by tensile tests performed on specimens having different orientations with respect to RD. Throughout this article, the (uniaxial) yield stress and the Lankford coefficient associated with a direction forming the angle θ with RD (Fig. 2) will be denoted by σ_θ and r_θ respectively.

The r_θ coefficient is defined by the following equation:

$$r_\theta = \frac{\varepsilon_{\theta+90^\circ}^p}{\varepsilon_{ND}^p}, \quad (4)$$

where $\varepsilon_{\theta+90^\circ}^p$ and ε_{ND}^p are the plastic parts of the logarithmic strain in the width and thickness directions, respectively. In the case of isotropic materials, r_θ equals 1 because the

Fig. 2 Tensile specimen cut at the angle θ with respect to RD

width and thickness strains have the same value. If r_θ is >1 , the width strains will be dominant. This is the case of anisotropic sheet metals exhibiting thinning resistance. The other case, when r_θ is <1 , is characteristic for anisotropic sheet metals exhibiting thinning predisposition.

As the thickness of the specimen is considerably smaller than its width, the measurement errors of the plastic strains ε_{ND}^p and $\varepsilon_{\theta+90^\circ}^p$ are quite different. Due to this fact, Eq. 4 is replaced by the relationship

$$r_\theta = -\frac{\varepsilon_{\theta+90^\circ}^p}{\varepsilon_\theta^p + \varepsilon_{\theta+90^\circ}^p}, \quad (5)$$

obtained with the help of the incompressibility condition

$$\varepsilon_\theta^p + \varepsilon_{\theta+90^\circ}^p + \varepsilon_{ND}^p = 0. \quad (6)$$

The quantity denoted by ε_θ^p in Eqs. 5 and 6 is the plastic part of the logarithmic strain in the axial direction.

The average of the r -values obtained for different directions in the surface of a metallic sheet is the so-called coefficient of normal anisotropy r_n . Having determined the r -values associated with the directions defined by the angles $\theta=0^\circ$, 45° , and 90° the coefficient of normal anisotropy is

$$r_n = \frac{1}{4}(r_0 + 2r_{45} + r_{90}). \quad (7)$$

The variation of the anisotropy in the surface of the metallic sheet is quantitatively described by

$$\Delta r = \frac{1}{2}(r_0 + r_{90} - 2r_{45}), \quad (8)$$

known as the planar anisotropy coefficient.

In order to get a more intuitive image of the anisotropy of sheet metals, a polar coordinate representation is frequently used. The diagram in Fig. 3^[2] gives such a representation for an aluminum alloy (AA5182-0). The polar diagram is preferred due to its capability to offer direct information on the earing predisposition of sheet metals subjected to deep-drawing. One may notice the symmetry of the curve with respect to the coordinate axes. This symmetry is a proof of the orthotropic behavior of the sheet metal.

Quantitative Description of Plastic Anisotropy in Balanced Biaxial Traction

The balanced biaxial traction is a plane stress state subjected to the constraints $\sigma_{11}=\sigma_{22}$ and $\sigma_{12}=0$. The common value of the tensile stresses $\sigma_{11}=\sigma_{22}=\sigma_b$ corresponding to the yielding initiation is the so-called balanced biaxial yield stress. This quantity can be determined by hydraulic bulge tests^[3] or balanced biaxial tensile tests performed on cruciform specimens.^[4]

Fig. 3 Variation of the Lankford coefficient in the surface of an AA5182-0 sheet metal

Fig. 4 Logarithmic strains measured on the specimen during the disk compression test

Source: From Barlat et al.^[5]

Experimental investigations have also proved that the yield surfaces are not symmetric in the balanced biaxial region.^[1,3,5] This fact is a consequence of the plastic anisotropy. In order to give a quantitative description of such a behavior, the so-called coefficient of biaxial anisotropy has been independently defined by Barlat et al.^[3] and Pöhlant et al.^[4] Barlat and his coworkers^[3,15] have proposed the use of a compression test for the experimental determination of this parameter. A set of circular specimens are subject to normal pressure in the case of this test. Due to the plastic anisotropy, the specimens become elliptic during the compression. The phenomenon can be

Fig. 5 Strains measured on the cross specimen during the biaxial tensile test

observed in Fig. 4 that shows the results of a compression test for an AA6111-T4 aluminum alloy sheet. By measuring the major and minor axes of the elliptic specimens, the corresponding principal strains can be evaluated. The ratio of these quantities will define the coefficient of biaxial anisotropy:

$$r_b = \frac{\epsilon_{TD}^p}{\epsilon_{RD}^p} = \frac{\epsilon_{22}^p}{\epsilon_{11}^p} \quad (9)$$

The r_b -parameter is a direct measure of the slope of the yield locus at the balanced biaxial stress state. If the material is isotropic, r_b will be 1. The more pronounced the anisotropy, the farther r_b is from unity. Pöhlant et al.^[4] have proposed using the biaxial tensile testing machine to determine this coefficient.

Figure 5 shows the method used for determining the principal strains on a biaxial testing machine. This experimental procedure is limited by the fact that the straining degree is rather small (<5%).

CLASSICAL YIELD CRITERIA FOR ANISOTROPIC SHEET METALS

Hill 1948 Yield Criterion

In 1948 Hill^[6] proposed an anisotropic generalization of the von Mises yield criterion. The material anisotropy is supposed to admit three orthogonal symmetry planes. The yield criterion is expressed by a quadratic function:

$$f(\sigma_{ij}) \equiv F(\sigma_{22} - \sigma_{33})^2 + G(\sigma_{33} - \sigma_{11})^2 + H(\sigma_{11} - \sigma_{22})^2 + 2L\sigma_{23}^2 + 2M\sigma_{31}^2 + 2N\sigma_{12}^2 \quad (10)$$

where f is the yield function, F, G, H, L, M , and N are material anisotropy constants. For plane stress conditions ($\sigma_{33} = \sigma_{31} = \sigma_{23} = 0; \sigma_{11} \neq 0; \sigma_{22} \neq 0; \sigma_{12} \neq 0$), the yield criterion becomes

$$2f(\sigma_{ij}) \equiv (G + H)\sigma_{11}^2 - 2H\sigma_{11}\sigma_{22} + (H + F)\sigma_{22}^2 + 2N\sigma_{12}^2 \quad (11)$$

The relations between the anisotropy coefficients and the coefficients $F, G, H, \dots$ may be easily obtained from the flow rule associated with the yield function:

$$r_0 = \frac{H}{G}; \quad r_{90} = \frac{H}{F}; \quad r_{45} = \frac{N}{F+G} - \frac{1}{2}. \quad (12)$$

In cases where the principal directions of the stress tensor are coincident with the anisotropy axes ($\sigma_{11} = \sigma_1, \sigma_{22} = \sigma_2, \sigma_{12} = 0$), the Hill 1948 yield criterion can be written in terms of the principal stresses as

$$\sigma_1^2 - \frac{2r_0}{1+r_0}\sigma_1\sigma_2 + \frac{r_0(1+r_{90})}{r_{90}(1+r_0)}\sigma_2^2 = \sigma_0^2. \quad (13)$$

From this equation, it follows that in order to define the yield under the plane stress condition, three mechanical parameters are needed, namely, the coefficients r_0 and r_{90} and one of the uniaxial yield stresses σ_0 and σ_{90} .

Eq. 13 geometrically represents the families of ellipses depending on the parameters r_0 and r_{90} . In case of a material exhibiting only normal anisotropy ($r_0 = r_{90} = r$), it follows that $\sigma_0 = \sigma_{90} = \sigma_u$ and Eq. 13 takes the simpler form:

$$\sigma_1^2 - \frac{2r}{1+r}\sigma_1\sigma_2 + \sigma_2^2 = \sigma_u^2. \quad (14)$$

Fig. 6 Influence of the normal anisotropy coefficient r on the shape of the Hill 1948 normalized yield surface

Figure 6 gives a graphical representation of the family of yield surfaces corresponding to Eq. 14 for different values of parameter r .

Hill's 1948 yield criterion combines several appealing advantages: it is mathematically simple, and its basic assumptions are easy to understand and the corresponding material parameters have a direct physical meaning.

Barlat 1989 Yield Criterion

Barlat and Richmond^[7] proposed a more general form of Hosford's criterion for isotropic materials^[8] by expressing it in an xyz coordinate system, not necessarily coincident with the principal directions (the so-called tri-component plane stress yield surface):

$$f = |k_1 + k_2|^M + |k_1 - k_2|^M + |2k_2|^M = 2\bar{\sigma}^M. \quad (15)$$

Here, k_1 and k_2 are the invariants of the stress tensor, and M is an integer exponent having the same significance as the exponent used by Hosford. k_1 and k_2 are obtained from:

$$k_1 = \frac{\sigma_{11} + \sigma_{22}}{2}, \quad k_2 = \sqrt{\left(\frac{\sigma_{11} - \sigma_{22}}{2}\right)^2 + \sigma_{12}^2}. \quad (16)$$

In 1989, Barlat and Lian^[9] published a generalization of Eqs. 15 and 16 for materials exhibiting planar anisotropy by introducing the following yield function:

$$f = b|k_1 + k_2|^M + b|k_1 - k_2|^M + c|2k_2|^M = 2\bar{\sigma}^M. \quad (17)$$

The coefficients k_1 and k_2 are given by

$$k_1 = \frac{\sigma_{11} + h\sigma_{22}}{2}, \quad k_2 = \left[\left(\frac{\sigma_{11} - h\sigma_{22}}{2} \right)^2 + p^2\sigma_{12}^2 \right]^{\frac{1}{2}}, \quad (18)$$

where b, c, h , and p are the material parameters (see Fig. 7).

In 1991, Barlat proposed a 3D extension of his yield criterion.^[5] Banabic et al.^[10–12] also proposed extensions of the Barlat 1989 yield criterion (with seven and eight coefficients), aiming to remove some of its intrinsic limitations.

ADVANCED ANISOTROPIC YIELD CRITERIA

During the past few years, the competition in the automotive and aeronautical industry has become more intense. This fact has led to the development of new steel alloys (bake hardenable, dual phase, complex phase, transformation-induced plasticity, martensitic steels, hot-stamping boron-alloyed steels), as well as aluminum alloys having better performances and an increased interest in the use of magnesium and superplastic alloys. Since 2000, the

Fig. 7 The non-quadratic yield function of Barlat 1989, normalized by σ_0 influence of the exponent M

modeling of the anisotropic behavior of these materials has encouraged the research activities focused on the development of yield criteria. Several new models have been proposed during the past few years. These models allow a very good description of the anisotropic behavior of steel alloys (body-centered cubic [BCC] crystallographic structure), aluminum alloys (face-centered cubic [FCC] structure), and magnesium alloys (hexagonal close-packed [HCP] structure). The new yield criteria incorporate a large number of coefficients (usually, at least eight coefficients). Due to this fact, they are able to give an accurate description of the yield surface and follow closely the planar variations of the uniaxial yield stress and the coefficient of plastic anisotropy. Even more, some of the recently developed models can also capture the non-symmetric response in tension/compression specific to the HCP alloys. Due to the significant impact of these advanced yield criteria, they are described in this distinct article.

Karafilis and Boyce Yield Criterion

In 1993, Karafilis and Boyce^[13] developed the idea of combining two different yield function expressions to increase the flexibility. Their yield function is written as

$$f = (1 - c)\phi_1 + c\phi_2 = 2\bar{\sigma}^M, \quad (19)$$

with

$$\begin{aligned} \phi_1 &= |\Sigma_1 - \Sigma_2|^M + |\Sigma_2 - \Sigma_3|^M + |\Sigma_3 - \Sigma_1|^M \\ \phi_2 &= \frac{3^M}{2^{m-1} + 1} \left(|\Sigma_1|^M + |\Sigma_2|^M + |\Sigma_3|^M \right), \end{aligned} \quad (20)$$

where Σ_i are the three principal values of the linearly transformed stress tensor $\Sigma = \mathbf{L} \cdot \boldsymbol{\sigma}$. The deviatoric operator $\mathbf{L}$ contains six anisotropy parameters. According to their defining equations, ϕ_1 represents a yield locus located between the Tresca yield locus and the von Mises yield locus, and ϕ_2 varies from the von Mises to a theoretical upper bound as m changes from 2 to ∞ .

The original Karafilis–Boyce yield surface had six parameters in the anisotropy matrix $\mathbf{L}$, along with parameters M and c , thus having more flexibility compared to other yield functions of the time. Their proposal of linear transformation of the actual stress tensor into an “isotropic plasticity equivalent” stress tensor as a means to introduce anisotropy in isotropic yield functions has been further adopted and extended by Barlat and coworkers in 2000 and 2014.

Barlat’s Yield Criteria

In order to cure the disadvantages of the Barlat 1994 and Barlat 1996 yield criteria while preserving their flexibility, Barlat proposed in 2000^[3,13] a new model particularized for plane stress (2D). Barlat considers a linear transformation defined as follows:

$$\Sigma = \mathbf{C} \cdot \mathbf{s}, \quad (21)$$

where $\mathbf{s}$ is the deviatoric stress tensor and Σ is the linearly transformed stress tensor. Matrix $\mathbf{C}$ contains nine independent anisotropy coefficients for the general case and seven for plane stress. However, when applied to plane stress conditions, only one coefficient is available to account for σ_{45} and r_{45} . As pointed out in the work of Barlat et al.,^[3,2] additional coefficients can be obtained by using two transformations associated with two different isotropic yield functions. As a consequence, Barlat et al.^[3] proposed a yield function expressed by the relationship

$$f = f' + f'' = 2\bar{\sigma}^M, \quad (22)$$

where

$$f' = |S_1 - S_2|^M \quad (23)$$

and

$$f'' = |2S_2 + S_1|^M + |2S_1 + S_2|^M. \quad (24)$$

S_1 and S_2 are the principal deviatoric stresses and M is an exponent depending on the crystallographic structure of the material. Applying a linear transformation to each of the isotropic functions defined by Eqs. 23 and 24, one obtains the yield function:

$$f = f'(\Sigma') + f''(\Sigma'') = 2\bar{\sigma}^M, \quad (25)$$

where $\bar{\sigma}$ is the effective stress, M is a material coefficient, and

$$\begin{aligned} f' &= |\Sigma'_1 - \Sigma'_2|^M \\ f'' &= |2\Sigma''_2 + \Sigma''_1|^M + |2\Sigma''_1 + \Sigma''_2|^M, \end{aligned} \quad (26)$$

while

$$\begin{aligned} \Sigma' &= \mathbf{C}' \cdot \mathbf{s} = \mathbf{C}' \cdot \mathbf{T} \cdot \boldsymbol{\sigma} = \mathbf{L}' \cdot \boldsymbol{\sigma} \\ \Sigma'' &= \mathbf{C}'' \cdot \mathbf{s} = \mathbf{C}'' \cdot \mathbf{T} \cdot \boldsymbol{\sigma} = \mathbf{L}'' \cdot \boldsymbol{\sigma}, \end{aligned} \quad (27)$$

where $\mathbf{T}$ is a matrix that transforms the Cauchy stress tensor $\boldsymbol{\sigma}$ into its deviator $\mathbf{s}$:

$$\mathbf{T} = \begin{bmatrix} 2/3 & -1/3 & 0 \\ -1/3 & 2/3 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad (28)$$

with $\mathbf{C}'$ and $\mathbf{C}''$ being the linear transformations. In the reference frame associated with the material symmetry,

$$\begin{bmatrix} \Sigma'_{11} \\ \Sigma'_{22} \\ \Sigma'_{12} \end{bmatrix} = \begin{bmatrix} C'_{11} & C'_{12} & 0 \\ C'_{21} & C'_{22} & 0 \\ 0 & 0 & C'_{66} \end{bmatrix} \begin{bmatrix} s_{11} \\ s_{22} \\ s_{12} \end{bmatrix} \quad (29)$$

and

$$\begin{bmatrix} \Sigma''_{11} \\ \Sigma''_{22} \\ \Sigma''_{12} \end{bmatrix} = \begin{bmatrix} C''_{11} & C''_{12} & 0 \\ C''_{21} & C''_{22} & 0 \\ 0 & 0 & C''_{66} \end{bmatrix} \begin{bmatrix} s_{11} \\ s_{22} \\ s_{12} \end{bmatrix}. \quad (30)$$

Because f' depends on $\Sigma'_1 - \Sigma'_2$, only three coefficients remain independent in $\mathbf{C}'$.^[2,3] There are five independent coefficients in $\mathbf{C}''$. In both transformations, there are eight independent anisotropy coefficients.

The principal values Σ_1 and Σ_2 of tensors Σ' and Σ'' are as follows:

$$\begin{aligned} \Sigma_1 &= \frac{1}{2} \left(\Sigma_{11} + \Sigma_{22} + \sqrt{(\Sigma_{11} - \Sigma_{22})^2 + 4\Sigma_{12}^2} \right) \\ \Sigma_2 &= \frac{1}{2} \left(\Sigma_{11} + \Sigma_{22} - \sqrt{(\Sigma_{11} - \Sigma_{22})^2 + 4\Sigma_{12}^2} \right). \end{aligned} \quad (31)$$

The coefficients of $\mathbf{C}'$ and $\mathbf{C}''$ are as follows:

$$\begin{bmatrix} L'_{11} \\ L'_{12} \\ L'_{21} \\ L'_{22} \\ L'_{66} \end{bmatrix} = \begin{bmatrix} 2/3 & 0 & 0 \\ -1/3 & 0 & 0 \\ 0 & -1/3 & 0 \\ 0 & 2/3 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_7 \end{bmatrix} \quad (32)$$

$$\begin{bmatrix} L''_{11} \\ L''_{12} \\ L''_{21} \\ L''_{22} \\ L''_{66} \end{bmatrix} = \frac{1}{9} \begin{bmatrix} -2 & 2 & 8 & -2 & 0 \\ 1 & -4 & -4 & 4 & 0 \\ 4 & -4 & -4 & 1 & 0 \\ -2 & 8 & 2 & -2 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \alpha_3 \\ \alpha_4 \\ \alpha_5 \\ \alpha_6 \\ \alpha_8 \end{bmatrix}$$

Due to the fact that eight coefficients are incorporated in the linear transformations, eight material characteristics are needed for identification. The uniaxial tension test along the rolling, diagonal, and transversal directions, together with the biaxial tension test can provide only seven characteristics (three uniaxial yield stresses, three coefficients of uniaxial anisotropy, and the biaxial yield stress). Barlat adopted the coefficient of biaxial anisotropy r_b as the eighth characteristic in the identification procedure.

By using the same methodology as the one described previously, Aretz and Barlat^[14] and Barlat et al.^[15] proposed a 3D yield criterion called Barlat2004–18p:

$$\begin{aligned} f &= |s'_1 - s''_1|^M + |s'_1 - s''_2|^M + |s'_1 - s''_3|^M + |s'_2 - s''_1|^M + |s'_2 - s''_2|^M + \\ &+ |s'_2 - s''_3|^M + |s'_3 - s''_1|^M + |s'_3 - s''_2|^M + |s'_3 - s''_3|^M = 4\bar{\sigma}^M, \end{aligned} \quad (33)$$

where $\bar{\sigma}$ represents the uniaxial yield stress (any other yield stress may be used as reference yield stress) and M is an exponent determined based on the crystallographic structure of the material. The associated linear transformation on the stress deviator is defined as follows:

$$\mathbf{C} = \begin{bmatrix} 0 & -c_{12} & -c_{13} & 0 & 0 & 0 \\ -c_{21} & 0 & -c_{23} & 0 & 0 & 0 \\ -c_{31} & -c_{32} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{66} \end{bmatrix} \quad (34)$$

and $\mathbf{C}'$ and $\mathbf{C}''$ are obtained by adding prime and double prime symbols. Each transformation provides 9 coefficients, and totally both transformations give 18 coefficients. In order to determine all these coefficients, the minimization of an appropriate error function is used.^[10] If only one linear transformation is assumed, the Barlat 2004–18p formulation reduces to the Barlat 1991 yield criterion.

The uniaxial yield stresses and anisotropy coefficients in seven directions in the plane of the sheet (0° , 15° , 30° , 45° , 60° , 75° , and 90° to the RD), the biaxial yield stress, the biaxial anisotropy coefficient, and four additional data characterizing out-of-plane properties (two tensile and two simple shear yield stresses) are used in the identification of all the coefficients. For determination of the out-of-plane parameters, crystal plasticity models are recommended.^[15,16]

The yield function has been tested for different aluminum alloys exhibiting a pronounced anisotropy. The model was able to predict very accurately the planar variations of the uniaxial yield stress and coefficient of plastic anisotropy in all cases.

The implementation of the Barlat 2004–18p model in finite-element codes^[16] has proved its capability to predict the occurrence of six and eight ears in the process of cup drawing. This is the most important advantage of the yield criterion. Of course, it is possible to develop models incorporating more and more linear transformations and thus having a larger number of coefficients. The practical difficulty related to the use of such yield criteria consists in the experimental determination of the mechanical parameters needed for the evaluation of the coefficients. The disadvantages of the models presented above are as follows:

- Due to the complexity of the formulation, they are not user-friendly.
- They need crystal plasticity models for the evaluation of some parameters.

Cazacu–Barlat Yield Criteria

To introduce orthotropy in the expression of an isotropic criterion, Cazacu and Barlat^[17] proposed an alternative method based on the representation of tensor functions. They developed a method of generalizations of the invariants of the stress deviator J_2 and J_3 . Based on this method, an anisotropic yield criterion is obtained by substituting the expression of the stress deviator invariants in the isotropic criterion by their respective anisotropic forms.

In the work of Cazacu and Barlat,^[17] this approach was used to extend Drucker's isotropic yield criterion^[18,19] to an orthotropic formulation. For this case, the expression of the proposed orthotropic criterion is as follows:

$$f = (J_2)^3 - c(J_3)^2 \leq k^2 \quad (35)$$

where c is a constant,

$$k^2 = 18 \left(\frac{\sigma_0}{3} \right)^6, \quad (36)$$

and σ_0 is the uniaxial yield stress—in the RD, for the anisotropic case.

For the plane stress case, the yield function may be written in the form:

$$f = \left[\frac{1}{6}(a_1 + a_3)\sigma_{11}^2 - \frac{a_1}{3}\sigma_{11}\sigma_{22} + \frac{1}{6}(a_1 + a_2)\sigma_{22}^2 + a_4\sigma_{12}^2 \right]^3 - c \left\{ \frac{1}{27}(b_1 + b_2)\sigma_{11}^3 + \frac{1}{27}(b_3 + b_4)\sigma_{22}^3 - \frac{1}{9}(b_1\sigma_{11} + b_4\sigma_{22})\sigma_{11}\sigma_{22} \right. \\ \left. - \frac{1}{3}\sigma_{12}^2[(b_3 - 2b_{10})\sigma_{11} - b_5\sigma_{22}] \right\}^2 \leq k^2 \quad (37)$$

where $a_1, \dots, a_4, b_1, \dots, b_5$ and b_{10} are the coefficients describing the anisotropy, c is a constant, and k is expressed by Eq. 36. As one may see, the yield function incorporates 10 anisotropy coefficients and an extra constant c . The 10 anisotropy coefficients and the value of c can be determined from the measured uniaxial yield stresses σ_θ and strain ratios r_θ in five different orientations, and σ_b is the value of the equibiaxial tensile stress. In the 3D case, the model incorporates 18 coefficients.

Cazacu and Barlat^[19] also applied the representation theorems for transverse isotropy and cubic symmetries. The general expressions of the invariants of the stress deviators in these conditions are presented in detail in.^[17] The method is applied for the extension of Drucker's isotropic yield criterion to transverse isotropy and cubic symmetries.

Aiming to develop the models of the asymmetrical tension/compression behavior specific to the alloys having an HCP structure, Cazacu and Barlat have successfully used the representation theory of tensor functions. In order to give a more straightforward physical meaning to the right-hand term in Eq. 35, they proposed an isotropic yield function in the form:^[20]

$$f = (J_2)^{3/2} - cJ_3 \leq \tau_y^3, \quad (38)$$

where τ_y is the yield stress in pure shear and c a constant that can be expressed in terms of the uniaxial yield stresses in tension σ_T and compression σ_C , respectively:

$$c = \frac{3\sqrt{3}(\sigma_T^3 - \sigma_C^3)}{2(\sigma_T^2 + \sigma_C^2)}. \quad (39)$$

Anisotropy was introduced in the formulation using the method presented above.

For plane stress conditions, the yield locus is as follows:

$$\left[\frac{1}{3}(\sigma_1^2 - \sigma_1\sigma_2 + \sigma_2^2) \right]^{3/2} - \frac{c}{27}[2\sigma_1^3 + \sigma_2^3 - 3(\sigma_1 + \sigma_2)\sigma_1\sigma_2] \leq \tau_y^3, \quad (40)$$

where σ_1 and σ_2 are the principal stresses.

The expressions of the anisotropic yield function and of the uniaxial yield stresses in tension and compression along an axis having the angular orientation θ to the RD are presented in.^[20] The predictions of the biaxial yield stresses corresponding to the tension and compression, as well as the planar distribution of the anisotropy coefficient, are also presented in the referenced paper.

Following several experimental researches^[21] on HCP alloys (e.g., titanium-based alloys), Cazacu et al.^[22] proposed the following isotropic yield function:

$$f = \|S_1 - kS_1\|^M + \|S_2 - kS_2\|^M + \|S_3 - kS_3\|^M, \quad (41)$$

where S_1 , S_2 , and S_3 are the principal values of the stress deviator, M is a positive integer, and k is the strength differential parameter.

In order to extend the isotropic criterion defined by Eq. 41 to an anisotropic formulation, the principal values of the deviatoric stress (S_1, S_2, S_3) are replaced by the principal values of the transformed tensor ($\Sigma_1, \Sigma_2, \Sigma_3$) obtained after applying a linear transformation. In this way, the new anisotropic yield criterion (CPB05) can be written as follows:

$$f = \left\| \Sigma_1 - k \Sigma_1 \right\|^M + \left\| \Sigma_2 - k \Sigma_2 \right\|^M + \left\| \Sigma_3 - k \Sigma_3 \right\|^M. \quad (42)$$

The paper^[22] gives a detailed presentation of the relationships used to predict the uniaxial yield stresses and the coefficients of plastic anisotropy for both tension and compression states. Additional linear transformations can be incorporated into the CPB05 criterion for an improved representation of the anisotropy. The most important advantage of this yield criterion consists of its capability to provide an accurate description of the tension/compression differential behavior specific to the magnesium and titanium alloys.

Vegter Yield Criterion

Using points of the yield locus determined directly by experiments, Vegter^[23,24] obtained the yield locus in the first quadrant by applying a Bézier interpolation. Vegter's criterion requires the determination of three parameters for each reference point (two principal stresses σ_1 and σ_2 and the plastic strain rate ratio $\rho = d\varepsilon_2^p/d\varepsilon_1^p$). In order to describe planar anisotropy Vegter's criterion needs as many as 17 parameters. The analytical expression of the criterion is

$$\begin{pmatrix} \sigma_1 \\ \sigma_2 \end{pmatrix} = (1-\lambda)^2 \begin{pmatrix} \sigma_1 \\ \sigma_2 \end{pmatrix}_i^r + 2\lambda(1-\lambda) \begin{pmatrix} \sigma_1 \\ \sigma_2 \end{pmatrix}_i^h + \lambda^2 \begin{pmatrix} \sigma_1 \\ \sigma_2 \end{pmatrix}_{i+1}^r \quad (43)$$

for σ_e and angle φ where

$$\begin{pmatrix} \sigma_1 \\ \sigma_2 \end{pmatrix}_{i+1}^r = \sum_{j=0}^m \begin{pmatrix} a_1^j \\ a_2^j \end{pmatrix}_i \cos(2j\varphi) \quad (44)$$

is a trigonometric expansion associated with the reference point,

$$R(\varphi) = \sum_{j=0}^m b^j \cos(2j\varphi) \quad (45)$$

is a cosine interpolation of the function $R(\varphi)$, φ is the angle between the principal directions and the orthotropy axes, λ is a parameter of the Bézier function, r is a superscript denoting the reference point, h is a superscript denoting the breaking point, $\begin{pmatrix} a_1^j \\ a_2^j \end{pmatrix}_i$ are the

Fig. 8 Control of Vegter's yield surface by means of experimental data referring to different stress states

parameters of the trigonometric interpolation to be determined at the reference points, and b^j are the parameters of the trigonometric interpolation of the R -function.

The most important advantage of the criterion is the flexibility ensured by the large number of parameters. The disadvantages are related to the unfriendly form of the yield function making it improper for analytical computation, the large number of experiments required (uniaxial tension, biaxial tension, plane strain, and pure shearing—see Fig. 8), and the need of mathematical abilities of the user. The Vegter model has been implemented in the AUTOFORM, PAMSTAMP, and LS-Dyna finite-element (FE) commercial programs.

BBC 2005 Yield Criterion

BBC 2005 is a flexible yield criterion that does not enforce some special constraints on the choice of the yield parameter Y (Eq. 1), although it is supposed to represent a yield stress.^[12,25] For example, Y may be the uniaxial yield stress σ_θ associated with a direction defined by the angle θ measured from RD, an average of several uniaxial yield stresses, or the balanced biaxial yield stress σ_b associated with RD and TD.

The BBC 2005 equivalent stress is defined by the following formula:^[25]

$$f = \bar{\sigma} = \left[a(\Lambda + \Gamma)^{2k} + a(\Lambda - \Gamma)^{2k} + b(\Lambda + \Psi)^{2k} + b(\Lambda - \Psi)^{2k} \right]^{\frac{1}{2k}} \quad (46)$$

where $k \in \mathbb{N}^*$ and $a, b > 0$ are the material parameters, while Γ , Λ , and Ψ are the functions depending on the planar components of the stress tensor:

$$\begin{aligned} \Gamma &= L\sigma_{11} + M\sigma_{22} \\ \Lambda &= \sqrt{(N\sigma_{11} - P\sigma_{22})^2 + \sigma_{12}\sigma_{21}} \\ \Psi &= \sqrt{(Q\sigma_{11} - R\sigma_{22})^2 + \sigma_{12}\sigma_{21}} \end{aligned} \quad (47)$$

The coefficients L, M, N, P, Q , and R involved in Eq. 47 are also material parameters.

Despite the fact that Eqs. 46 and 47 do not enforce any constraint on the sign of these six coefficients, the

numerical tests performed by the authors have shown that positive values of these parameters lead to better predictions of the BBC 2005 yield criterion.

The conditions $k \in \mathbb{N}^{\geq 1}$ and $a, b > 0$ ensure the convexity of the yield surface defined in Eqs. 46 and 47. The parameters L, M, N, P, Q , and R are not subjected to any constraint from this point of view.

Nine material parameters are involved in the expression of the BBC 2005 equivalent stress: k, a, b, L, M, N, P, Q , and R (see Eqs. 46 and 47). The integer exponent k has a special status, due to the fact that its value is fixed from the very beginning in accordance with the crystallographic structure of the material: $k=3$ for BCC materials and $k=4$ for FCC materials.

The identification procedure calculates the other parameters by forcing the constitutive equations associated with the BBC 2005 yield criterion to reproduce the following experimental data:

- The uniaxial yield stresses associated with the directions defined by $0^\circ, 45^\circ$, and 90° angles measured from RD (denoted as σ_0, σ_{45} , and σ_{90}).
- The coefficients of uniaxial plastic anisotropy associated with the directions defined by $0^\circ, 45^\circ$, and 90° angles measured from RD (denoted as r_0, r_{45} , and r_{90}).
- The biaxial yield stress associated with RD and TD (denoted as σ_b).
- The coefficient of biaxial plastic anisotropy associated with RD and TD (denoted as r_b).

There are eight constraints acting on eight material parameters. The identification procedure has enough data to generate a set of equations having a, b, L, M, N, P, Q , and R as unknowns.

BBC 2008 Yield Criterion

In order to enhance the flexibility of the BBC 2005 yield criterion, a new version of this model has been developed.^[26] The model is expressed as a finite series that can be expanded to retain more or less terms, depending on the volume of experimental data. Different identification strategies (using 8, 16, 24, etc. input values) could be used in order to determine the coefficients of the yield function.

The equivalent stress is defined as follows:

$$f = \frac{\bar{\sigma}^{2k}}{w-1} = \sum_{i=1}^s \left\{ w^{j-1} \left[\left[L^{(i)} + M^{(i)} \right]^{2k} + \left[L^{(i)} - M^{(i)} \right]^{2k} \right] + w^{s-i} \left[\left[M^{(i)} + N^{(i)} \right]^{2k} + \left[M^{(i)} - N^{(i)} \right]^{2k} \right] \right\} \quad (48)$$

$$k, s \in \mathbb{N}^*, w = (3/2)^{1/s} > 1$$

$$L^{(i)} = \ell_1^{(i)} \sigma_{11} + \ell_2^{(i)} \sigma_{22}$$

$$M^{(i)} = \sqrt{\left[m_1^{(i)} \sigma_{11} - m_2^{(i)} \sigma_{22} \right]^2 + \left[m_3^{(i)} (\sigma_{12} + \sigma_{21}) \right]^2}$$

$$N^{(i)} = \sqrt{\left[n_1^{(i)} \sigma_{11} - n_2^{(i)} \sigma_{22} \right]^2 + \left[n_3^{(i)} (\sigma_{12} + \sigma_{21}) \right]^2}$$

$$\ell_1^{(i)}, \ell_2^{(i)}, m_1^{(i)}, m_2^{(i)}, m_3^{(i)}, n_1^{(i)}, n_2^{(i)}, n_3^{(i)} \in \mathbb{R}.$$

The quantities denoted $k, \ell_1^{(i)}, \ell_2^{(i)}, m_1^{(i)}, m_2^{(i)}, m_3^{(i)}, n_1^{(i)}, n_2^{(i)}, n_3^{(i)}$ ($i=1, \dots, s$) are material parameters. One may prove that $k \in \mathbb{N}^*$ is a sufficient condition for the convexity of the yield surface defined by Eq. 48. From this point of view, there is no constraint acting on the admissible values of the other material parameters.

It is easily noticeable that Eq. 48 reduces to the isotropic formulation proposed by Barlat and Richmond^[7] if

$$\begin{aligned} \ell_1^{(i)} &= \ell_2^{(i)} = m_1^{(i)} = m_2^{(i)} = m_3^{(i)} = n_1^{(i)} \\ &= n_2^{(i)} = n_3^{(i)} = 1/2, \quad i = 1, \dots, s. \end{aligned} \quad (49)$$

Under these circumstances, the exponent k may be chosen as in Barlat and Richmond's model, i.e., according to the crystallographic structure of the sheet metal.

The other parameters involved in Eq. 48 result from an identification procedure (see below). Their number n_p is defined by the number of terms S in the summation, and it should be smaller than the number of experimental values n_e available for the parameter identification

$$n_p = 8s \leq n_e \quad (50)$$

or, in other words,

$$s \leq n_e/8, \quad s \in \mathbb{N}^*. \quad (51)$$

Apparently, Eq. 48 can only be used when $n_e \geq 8$. In fact, it also works with less experimental values, which confers additional flexibility to the user. When such a situation occurs, the summation limit should be $s=1$, and the $n_e < 8$ identification constraints arisen from experiments should be accompanied by at least $8-n_e$ artificial conditions involving the material parameters. For example, if $n_e=6$, one may enforce the equalities $m_1^{(1)}=n_1^{(1)}$ and $m_2^{(1)}=n_2^{(1)}$. Of course, the prediction accuracy will be lower compared to the usage of eight input values, but the user does not need to select a different yield function depending on the available data.

An identification procedure that strictly enforces a large number of experimental constraints on the yield criterion would be inefficient in practical applications. The failure probability of such a strategy increases when the external restrictions become stronger. Taking into account this aspect, the authors have developed an identification procedure based on the minimization of the following error function:

$$E \left[\ell_1^{(i)}, \ell_2^{(i)}, m_1^{(i)}, m_2^{(i)}, m_3^{(i)}, n_1^{(i)}, n_2^{(i)}, n_3^{(i)} \mid i = 1, \dots, s \right] = \sum_{\theta_j} \left[\frac{\sigma_{\theta_j}^{(\text{exp})}}{\sigma_{\theta_j}} - 1 \right]^2 + \sum_{\theta_j} \left[r_{\theta_j}^{(\text{exp})} - r_{\theta_j} \right]^2 + \left[\frac{\sigma_b^{(\text{exp})}}{\sigma_b} - 1 \right]^2 + \left[r_b^{(\text{exp})} - r_b \right]^2, \quad (52)$$

where θ_j represents an individual element from a finite set of angles defining the orientation of the specimens used

in the uniaxial tensile tests. One may notice that Eq. 52 describes a square distance between the experimental and predicted values of the anisotropy characteristics.

Two versions of the BBC 2008 yield criterion have been evaluated from the point of view of their performances.^[26] They include 8 and 16 material coefficients, respectively, and correspond to $s=1$ and $s=2$, respectively. The identification of the BBC 2008 (16 parameters) model has been performed using the following mechanical parameters: $\sigma_0^{(exp)}$, $\sigma_{15}^{(exp)}$, $\sigma_{30}^{(exp)}$, $\sigma_{45}^{(exp)}$, $\sigma_{60}^{(exp)}$, $\sigma_{75}^{(exp)}$, $\sigma_{90}^{(exp)}$, $\sigma_b^{(exp)}$, $r_{0^\circ}^{(exp)}$, $r_{15^\circ}^{(exp)}$, $r_{30^\circ}^{(exp)}$, $r_{45^\circ}^{(exp)}$, $r_{60^\circ}^{(exp)}$, $r_{75^\circ}^{(exp)}$, $r_{90^\circ}^{(exp)}$, and $r_b^{(exp)}$. In the case of BBC 2008 (eight parameters), the input data have been restricted to the values $\sigma_0^{(exp)}$, $\sigma_{45}^{(exp)}$, $\sigma_{90}^{(exp)}$, $\sigma_b^{(exp)}$, $r_{0^\circ}^{(exp)}$, $r_{45^\circ}^{(exp)}$, $r_{90^\circ}^{(exp)}$, and $r_b^{(exp)}$.

As the flexibility of the models increase, more input parameters can be taken into account. However, the parameter identification becomes a critical step in order to achieve the full potential of the model. At some point, it becomes very difficult to increase the number of relevant experimental measures that can be used. In order to improve the parameter robustness, several authors proposed to use the prediction of crystal plasticity models as reference data for parameter identification.^[27] Gawad and coworkers^[28] developed an enhanced identification procedure for the BBC family of criteria, incorporating a larger number of values in the objective function (Eq. 52), determined by a crystal plasticity model. These include both the stress value and the outer normal to the yield surface at a series of stress points distributed over the areas of the yield surface that are difficult, or even impossible to explore by experiments. The result is an enhanced accuracy of the overall prediction capability of the models. An additional advantage of this procedure is the possibility to update the parameters during the straining history, in order to account for the texture evolution as described by the crystal plasticity model, resulting in a powerful hierarchical multiscale model.^[28]

PRACTICAL APPLICATION OF YIELD CRITERIA FOR PROCESS SIMULATION

Mechanical Parameters and Parameter Identification

Table 1 summarizes the mechanical parameters needed for the identification of the yield criteria reviewed above. The number of experimental tests and the corresponding costs required for the identification are different from one criterion to another. In particular, the determination of the biaxial yield stress and biaxial anisotropy coefficient requires specific equipment in order to perform cross tensile tests, hydraulic bulge tests, or disk compression, respectively. The following notations have been used in Table 1: 3D signifies the fact that the model can be used/extended for arbitrary 3D stress states; A1 shows that the yield criterion is able to describe “the first-order

anomalous behavior”;^[29] and A2 shows that the yield criterion is able to describe “the second-order anomalous behavior”.^[30]

Availability of the Yield Criteria in Numerical Simulation Software

The usage of advanced models is subject to several limitations. As already underlined, the determination of the necessary input parameters requires specific equipment and identification skills. Furthermore, these models are not always available in commercial finite-element software available for sheet metal forming simulation. Table 2 illustrates the availability of some of the yield criteria in finite-element software used by both industry and academia. Not all models are available in all software, which is a limiting factor in their application.

Comparison of the Yield Criteria

At present, the most frequently used yield criteria are Hill 1948, Hill 1990, and Barlat 1989. In this section, these models are used as reference for the comparison with one of the advanced yield criteria, namely, BBC 2008. Several performance indicators are used to compare these models: prediction of the yield locus shape, and description of the planar distribution of the uniaxial yield stress and of the uniaxial coefficient of plastic anisotropy. The aluminum alloy AA6016-T4 serves as the test material for the comparison.

Figure 9 shows the normalized yield loci predicted by Hill 1948, Barlat 1989, Barlat 2000, and BBC 2008 yield criteria together with experimental data.^[1,31] One may notice that the best predictions are provided by the BBC 2008 and Barlat 2000 models, whereas the performances of the Hill 1948 and Barlat 1989 models are unsatisfactory, especially in the biaxial tension region.

The planar distribution of the uniaxial yield stresses predicted by the models is shown in Fig. 10. As one may notice, BBC 2008 and Barlat 2000 have better performances. The less accurate predictions of the Hill 1948 and Barlat 1989 models can be related to the fact that the yield stress measured in the RD could be used for the parameter identification.

The predictions of the uniaxial coefficient of plastic anisotropy (Fig. 11) are similar with all models, since the same three experimental r -values were used to identify all models.

These results show that the parameter identification should include both the yield stresses and the strain ratios from uniaxial tensile tests performed in three directions of the sheet metal (at 0° , 45° , and 90° with respect to the RD). Furthermore, the biaxial tension experimental information should also be used—at least the strain ratio. Accordingly, the yield criterion will have to fit a minimum of seven mechanical parameters.

In these circumstances, when the same seven mechanical parameters are used for the parameter identification, all the tested models provide almost the same predictions of the anisotropic behavior for usual materials. This is illustrated in Fig. 12. The predictions of three

of the most recently developed models, namely, Barlat 2000, Cazacu-Barlat, and BBC 2000, are compared. An AA3103-0 aluminum alloy has been used in order to evaluate the accuracy of the predictions.^[32,33] The yield locus for this material was measured in the first quadrant using biaxial tensile testing of cruciform specimens,^[33] and it was predicted with the Barlat 2000, Cazacu-Barlat, and BBC2000 yield functions.

Figure 13 shows the experimental normalized yield stress and r -value as a function of the tensile direction for an AA 3103-0 aluminum alloy sheet sample. The three

models are able to capture tensile anisotropy and the yield locus shape of this alloy very well.

The yield criteria that use a larger number of mechanical parameters in the identification (13 or even more—Barlat 2004, BBC 2008, etc.) are able to provide highly accurate descriptions of the anisotropic behavior. In particular, these models are able to predict the occurrence of six or eight ears in the case of deep drawing of cylindrical cups.^[16,17,34]

The ability of BBC 2008 (16 parameters) to predict a complex earing profile in cylindrical cup drawing is illustrated in Fig. 14, along with other available models.^[31]

CONCLUSIONS

The selection of a yield criterion in view of applications is made difficult by their number, mathematical complexity, nonstandard parameter identification procedure, and availability in FE codes. The concluding remarks below are aimed to guide the user in this choice.

Recommendations on the Choice of the Yield Criteria

Several factors must be considered when choosing a yield criterion for applications:

- Accuracy of the prediction of both the yield locus and the uniaxial yield stress and uniaxial coefficient of plastic anisotropy.
- Computational efficiency and ease of implementation in numerical simulation codes.
- Flexibility of the yield criterion.
- Degree of generality.
- Number of mechanical parameters needed by the identification procedure.
- Robustness of the identification procedure.
- Experimental difficulties caused by the determination of the mechanical parameters involved in the identification procedure.
- User-friendliness of the yield criterion.
- Acceptance of the yield criterion in the scientific/ industrial community.

Usually, the best quality of the predictions will be ensured by the yield criteria having an identification procedure based on both uniaxial and biaxial tension experimental data. Concerning the experimental data obtained by uniaxial tensile tests, the identification should use both the yield stresses and the coefficients of plastic anisotropy, corresponding to at least three in-plane directions (0° , 45° , and 90°).

Excellent accuracy can be obtained with the yield criteria using larger numbers of experiments for the identification (13 or even more—Barlat 2004, Soare 2007, BBC 2008, etc.). The flexibility of these advanced models allows for the prediction of complex earing profiles in cup drawing, which illustrate their ability to describe realistically the anisotropic in-plane strain distributions.^[35–37]

Perspectives

As already shown in the previous sections, advanced yield criteria allow accurate prediction of the anisotropic behavior of materials. They can simultaneously describe the distribution of both the uniaxial yield stress and the anisotropy coefficient in the surface of the sheet metal. Aluminum alloys are particularly challenging in this respect as they exhibit the so-called first- and second-order

anisotropic behavior anomalies, which are also described by the advanced yield functions.

Future developments in this field may lead to new models that include special properties (superplastic materials, shape memory alloys, etc.). For complex loading paths, it could become necessary to consider the evolution of the parameters of the yield functions in order to describe the effect of texture evolutions. The material variability is an important topic that could be tackled by stochastic modeling. Coupling the phenomenological models with the ones based on crystal plasticity will allow better simulation of the parameter evolution in technological processes (including temperature, strain rate, strain path, and structural evolution).

Therefore, the virtual process chain will be described more accurately, improving the virtual design and validation of real manufacturing processes.

Anodic Oxides: Applications and Trends in Nanofabrication

W.J. Stepniowski

Department of Advanced Materials and Technologies, Faculty of Advanced Technology and Chemistry, Military University of Technology, Warsaw, Poland

Abstract

Anodic aluminum oxide (AAO) is one of the most frequently fabricated materials with the use of electrochemical techniques. In this article, current trends in aluminum anodizing are reviewed, including anodizing in novel electrolytes, anodizing in electrolytes with various additives, and fabrication of 3D nanostructures using pulse anodizing, leading to the formation of distributed Bragg reflectors. Applications of AAO in the field of nanofabrication are also reviewed with the use of milestone and the most current research.

Keywords: AAO; Anodic aluminum oxide; Anodic porous alumina; Anodizing; Nanofabrication; Nanopores; Nanotechnology; Templates.

LIST OF ACRONYMS

AAO—Anodic aluminum oxide
 ALD—Atomic layer deposition
 APTES—(3-aminopropyl)trimethoxysilane
 BLT—(Electrochemical) barrier layer thinning
 CVD—Chemical vapor deposition
 DBR—Distributed Bragg reflectors
 DC—Direct current
 EDTA—Ethylenediaminetetraacetic acid
 EG—Ethylene glycol
 FE-SEM—Field emission scanning electron microscope
 FOTS—Perfluorooctyltrichlorosilane
 HA—Hard anodization
 HAADF-STEM—High-angle annular dark-field scanning transmission electron microscopy
 IC—Indigo carmine
 INAAF—Inverted nanoporous anodic alumina funnels
 LOD—Limit of detection
 MA—Mild anodization
 MPTMS—3-(mercaptopropyl)-trimethoxysilane
 MWCNT—Multiwalled carbon nanotubes
 NAAF—Nanoporous anodic alumina funnels
 NT—Nanotubes
 NW—Nanowires
 P3HT—Poly(3-hexylthiophene)
 PL—Photoluminescence
 PPy—Polypyrrole
 RIFS—Reflectometric interference spectroscopy
 SERS—Surface-enhanced Raman spectroscopy

INTRODUCTION

Anodic oxidation of aluminum is a well-known industrial process applied to numerous elements such as parts for vehicles, aircraft, containers, or even window frames. During the process, aluminum is the anode and is electrochemically oxidized. As a result, anodic oxide is formed. The main purpose of aluminum anodizing is the formation of compact insulating layer on the protected element. Then, a corrosive cell will not be formed and corrosion will not occur. Additionally, the element gains a hard coating with an additional decorative effect. In industrial practice, a cleaned aluminum surface is anodized in sulfuric or chromic acid (however, recently the use of hexavalent chromium is controversial due to its toxicity). As a result, a porous oxide is formed on the surface. Next, to provide an aesthetic effect, dyeing of the material is conducted where a dye is adsorbed on the porous surface. The last step is sealing of the pores to provide a smooth, hard, and aesthetic protective surface coating. The sealing process is conducted in hot water or steam, aqueous solutions of cobalt and nickel salts, or sodium dichromate solutions.

Although anodic oxidation of aluminum has been known for over a century, there continues to be considerable ongoing research in this technology area. Typically, a porous oxide is composed of capillary structures with varied morphology. However, in 1995 Masuda and Fukuda reportedly obtained a highly ordered, nanoporous, aluminum oxide by using a two-step, self-organized anodization.^[1] Briefly, after the first step of anodization, they obtained a nanoporous

oxide that was selectively removed, after which hexagonally arranged nano-concaves were found on the surface. After re-anodizing using the same operating conditions, they obtained a highly ordered nanoporous morphology of the oxide. This was a breakthrough in nanofabrication and electrochemical materials science. Since then, research has focused on anodic alumina template-based synthesis of various nanowires, nanotubes (NTs), and nanodots made of a wide variety of materials.^[2]

Fundamentals of Aluminum Anodizing

Figure 1 depicts schematically a system for anodization. In such a system, two electrodes are employed: cathode (graphite plate or Pt grid) and aluminum anode, on which the oxide is growing. To maintain a constant temperature, the experiments are usually carried out in double-walled cells, plugged into thermostat with circulator. There are two approaches to perform anodization: galvanostatic and potentiostatic. In both approaches, direct current (DC) power supply is applied. In the potentiostatic approach, the oxide grows at a fixed voltage, and current density vs. time is recorded (galvanometer is plugged in series, like in Fig. 1). The current density changes in time are related to the phenomena occurring during the anodic oxide growth. In the galvanostatic approach (which is rarely used), a constant current density is kept and the voltage is being recorded (voltmeter is plugged parallelly then). Changes of the voltage in time are related to the occurring phenomena.

During anodic oxide growth, numerous reactions take place. On the anode, oxidation of aluminum takes place, according to the following half-cell reactions:

and aluminum oxide is formed. On the cathode, reduction of water and oxygen takes place, providing OH^- anions, required for the following anodic reactions:

Morphology of Anodic Aluminum Oxide

Anodic aluminum oxide (AAO) is composed of an array of hexagonally arranged parallel capillaries that grow perpendicularly to the metallic substrate (Fig. 2). The morphology of the AAO can be quantitatively described

Fig. 1 A scheme showing the system for anodizing with reactions occurring during the process

Fig. 2 A scheme of cross section (A) and top view (B) of AAO and top-view field emission scanning electron microscope (FE-SEM) image of the morphology of AAO formed in 0.3 M oxalic acid at 50°C, 40 V (C)

by pore diameter (D_p), interpore distance (D_c), thickness of the barrier layer grown (B), and total thickness of the grown oxide (L) (Fig. 2A,B). A model structure (Fig. 2A and B) looks like an ideally ordered honeycomb; however, the morphology of the obtained samples reveals a domain morphology (Fig. 2C). In the domain, the pores are ideally, hexagonally arranged (each pore has six neighbors), although at the domain boundaries, defective pores are common (a defective pore has five or seven neighbors).

Influence of the Operating Conditions on the Anodic Alumina Growth

Depending on the operating conditions, the morphology of nanoporous aluminum oxide differs. One of the first systemic studies on the influence of the operating conditions on the morphological features was reported by Ono et al.^[3,4] It was shown that during anodization in sulfuric, oxalic, chromic, and phosphoric acids, the pore diameter and interpore distance increased linearly with the

voltage. Simultaneously, depending on the electrolyte, at the same anodizing voltage, the pore diameter varies. The smallest pore diameter was reported for AAO formed in sulfuric acid, and the largest diameter for those obtained in phosphoric acid.^[3] Additionally, it was reported that independently from the applied electrolyte, the interpore distance increased linearly with the voltage.^[3,4] Moreover, the dissociation constant of the electrolyte determines the voltage range at which AAO can be formed. Ono et al. reported that for sulfuric acid, anodizing at 25 V allows the formation of AAO with $D_c = 65$ nm, whereas for oxalic acid, anodizing at 40 V forms AAO with $D_c = 100$ nm.^[4] It was shown that an interpore distance-to-voltage ratio is 2.5 nm/V, which is independent of the applied electrolyte (in this study, phosphoric, malonic, tartaric, and citric acids were also studied).

Recently, numerous systemic studies of the influence of the operating conditions on the morphological features of AAO have been reported. The influence of the electrolyte type, concentration and temperature, anodizing voltage, duration of anodizing and electrolyte viscosity on the oxide growth rate, pore diameter, interpore distance, pore density, porosity, and thickness of barrier layer has been reported, which provided quantitative relationships allowing researchers to obtain AAO with the desired morphology. It was shown that the pore diameter and the interpore distance increase linearly with the anodizing voltage.^[3–14] Moreover, the pore diameter increases with the temperature and duration of anodizing due to the field-assisted etching of the grown oxide,^[7,8,11,14] whereas the interpore distance remains unchanged. In Table 1, the relationships between the pore diameter (D_p) and the voltage (U), the interpore distance (D_c) and U as well as the oxide growth rate (H) and U were gathered for sulfuric,^[5,6] oxalic,^[8–11] phosphoric,^[12,13] and chromic acid.^[14] It can be easily inferred from Table 1 that for AAO formed in sulfuric acid, the pore diameters range from 13.1 nm (15 V, -8°C ^[6]) to 27.3 nm (25 V, 10°C ^[6]), whereas the interpore distance at the same electrolyte ranges from 39.8 nm (15 V, -8°C ^[6]) to 64.7 nm (25 V, -8°C ^[6]). Analogously, based on the fitted curves, the pore diameter and interpore distance can be estimated (Table 1). Additionally, the oxide growth rate increases exponentially with voltage and is accelerated when the electrolyte temperature is increased (Table 1). It was also found that the oxide growth rate decreases with increasing viscosity^[15] and the interpore distance increases linearly with the logarithm of electrolyte viscosity.^[15]

Based on the values of the pore diameter (D_p) and interpore distance (D_c), further morphological features can be estimated from the experimental results.^[15,16] For example, the wall thickness (W) of porous alumina can be estimated from the following equation:^[16]

$$W = \frac{D_c - D_p}{2} \quad (8)$$

Although the thickness of the barrier layer (B) at the bottom of the pore may be estimated from the following equation:^[16]

$$B = \frac{D_c - D_p}{1.42} \quad (9)$$

From these equations, it can be inferred that the greater the pore diameter at a fixed interpore distance (for what may be achieved by anodization at higher temperatures or for longer times, see Table 1), the lower the thickness of the anodic alumina walls and the barrier layer at the bottom of the pores. Porosity (α) may also be estimated from the pore diameter (D_p) and interpore distance (D_c):

$$\alpha = 0.907 \left(\frac{D_p}{D_c} \right)^2 \quad (10)$$

In this case, an increase in the electrolyte temperature or duration of the second step of the anodization process increases the pore diameter and porosity. Additionally, porosity is a square function of anodizing voltage.^[7,8] Another morphological parameter strongly linked to the operating conditions is the number of pores occupying a certain area (pore density). The pore density (n) is related to the interpore distance (D_c). For an ideally organized hexagonal lattice, the relationship between the pore density (number of pores per $1 \mu\text{m}^2$) and the interpore distance is given by following equation:^[15,16]

$$n = \frac{10^6}{\sqrt{3} \cdot D_c^2} \quad (11)$$

While taking into consideration the relationship between the interpore distance and the voltage for an ideally arranged hexagonal morphology,^[3,4] the following relationship can be obtained:^[15]

$$n = \frac{9.24 \cdot 10^4}{U^2} \quad (12)$$

Thus, the number of pores (n) decreases with voltage (U) as an inversed square of U . As with the interpore distance, the pore density is influenced by voltage, but there is neither temperature nor time effect.^[15]

The growth of anodic oxide obeys Faraday's law; thus, current density is a linear correlation with the thickness of the grown oxide (and oxide growth rate).^[15,16] Current density growth during the anodization process may provide information about the phenomena occurring during oxide growth. For aluminum anodizing, the current density–time transient illustrates the phenomena occurring during the first stages of the oxide growth. According to Parkhutik and Shershusky,^[17] the current density behavior with respect to time (Fig. 3) can be explained by the following:

Fig. 3 Aluminum anodized in 1.0M H_2SO_4 at 0°C , 20 V

1. Current drop corresponding to the formation of the insulating anodic alumina barrier layer at the aluminum/electrolyte interface.
2. Decrease in the rate of current density drop linked to the appearance of the first cracks in the barrier oxide formed.
3. Current density increase corresponding to the nucleation of pores.
4. Constant current density with respect to time corresponding to the steady growth of nanoporous AAO.

Current density is influenced by various operating conditions. It increases exponentially with anodizing voltage^[5–9,14,15] and increases linearly with anodizing temperature.^[8] Not only the operating conditions (voltage and temperature) but also the properties of the applied electrolyte influence the current density (j):^[15]

$$j = \frac{\alpha c_0 e^2 \left(\frac{z_+^2}{a_+} + \frac{z_-^2}{a_-} \right) E}{6\pi\eta} \quad (13)$$

where α is the dissociation fraction of the electrolyte, c_0 is the concentration of the electrolyte, e is the elemental charge, $z_{+,-}$ is the ions charge coefficient, $a_{+,-}$ is the hydrodynamic radius of the ion, E is the electric field intensity, and η is the viscosity of the electrolyte.

As stated previously, the anodizing voltage range is determined by the applied electrolyte. Below this range, nonporous oxide may be formed; however, above the critical voltage, a field-assisted anodic dissolution of the metal occurs, destroying the anode material. Nevertheless, increased current density would permit much

faster formation of anodic alumina. Therefore, hard anodization has been invented. The major “trick” bypassing anode “burning,” which is caused by an excessive current density at voltages above the critical value, is the formation of an insulating, protective layer first within the low current density range and then a stepwise increase of the voltage. For example, classical anodization, known also as mild anodization (MA), is conducted in sulfuric acid at 15–25 V. After the formation of the protective layer at voltages within this range, further anodization, known as hard anodization, can be conducted in the range of 40–70 V, which provides an anodic alumina with an interpore distance ranging from 90 to 140 nm (whereas MA provides an interpore distance at lower values; see Table 1).^[18] Analogously, MA voltage range for oxalic acid is 5–100 V, whereas for HA it is 110–150 V. Additionally, the oxide growth rate is strongly increased. According to Lee et al.,^[18] anodization of aluminum in oxalic acid at 1°C, 40 V results in anodic oxide growth rate ~2 µm/h, while at the same electrolyte and temperature, but for HA range it is ~70 µm/h. Furthermore, HA provides much better quality of nanopore arrangement, which is close to the required hexagonal honeycomb at large surfaces. It can be inferred from this information for the use of HA that a wide voltage range may be applied for aluminum anodizing. This fact led to the development of pulse anodizing: a method where subsequent MA and HA pulses are applied. Lee et al. reported first this approach to form 3D periodic structures^[19] (to be discussed in subsequent paragraphs).

There are also some issues related to hard anodizing. The first is the need for the formation of a protective layer prior to anodizing at the HA voltage range. However, during the HA, high current densities are recorded that are responsible for excessive heat formation. Therefore, rapid heat transfer from the anodized surface to the electrolyte bulk is another issue that had to be overcome. To dissipate the heat from the anode, various alcohol additives are applied, especially ethanol^[20] and ethylene glycol (EG).^[21] Current densities recorded during anodization in ethanol- and EG-containing electrolytes are lower due to the lower electrolyte conductivity, and consequently, less heat is generated at the anode/electrolyte interface.

CURRENT TRENDS IN ALUMINUM ANODIZING

In addition to MA and HA procedures in classical electrolytes, aluminum anodizing fundamentals have been reported. Recently, anodizing in new electrolytes and in electrolytes with various additives has been reported. Currently anodizing permitted the formation of various 3D nanostructures made of alumina, and interactions between light and matter allowed for structural color generation.

Novel Electrolytes

Typically, aluminum is anodized in three major electrolytes: sulfuric, oxalic, and phosphoric acids. However, to increase the range of experimental procedures, including voltage, new compounds have been reported as electrolytes for anodizing. Recently, fabrication of nanoporous AAO in citric acid,^[22] croconic acid,^[23] etidronic acid,^[24,25] malic acid,^[26] phosphonic acid,^[27] phosphonoacetic acid,^[28] pyrophosphoric acid,^[29–31] rhodizonic acid,^[23] selenic acid,^[32–35] squaric acid,^[36] and tartaric acid^[37,38] has been reported. Table 2 summarizes the novel electrolytes and major findings linked to their use in anodizing. Anodization in citric acid led to the formation of anodic alumina with micron-scale interpore distances (interpore distances up to 1420 nm have been reported).^[22] Kikuchi et al. reported a structural color generation with the use of etidronic acid (wavelength in the range of 400–800 nm)^[24,25] and phosphonoacetic acid (wavelength in the range of 500–700 nm),^[28] whereas the interpore distance of anodic alumina formed in these electrolytes was in the range of 530–670 nm and 500–550 nm, respectively. It was found that not only pore morphology but also the type of the electrolyte influence the optical properties of the AAO. This is caused by electrolyte anion incorporation into the anodic alumina walls. The positively polarized anode attracts negatively charged electrolyte anions that are adsorbed on the oxide surface, which further grows and traps them. Kikuchi et al. presented elemental maps of anodic alumina formed in phosphonic acid (Fig. 4).^[27] The elemental maps show that a significant amount of phosphorus, due to the electrolyte anions, is present in the oxide walls and that the incorporated anions exhibit a significant influence on the properties of the oxide. Vrublevsky et al. reported anodization in tartaric acid.^[37] Typically, a bandgap of AAO equals 6.5 eV, but incorporation of the tartrate anions decreases the bandgap to 3.25 eV. Furthermore, heat treatment of the anodic alumina samples with incorporated electrolyte anions allowed the tuning of the bandgap to 3.35 and 3.5 eV with annealing temperatures of 500°C and 700°C, respectively. Typically, nanoporous AAO is considered to impart hydrophobicity of the surface. Anodizing in pyrophosphoric acid allowed the formation of hexagonally ordered nano-needles that provided superhydrophilicity due to the geometry.^[31] In extreme situations, the wetting contact angle was as low as 1°.

Anodization in Electrolytes with Additives

Recently, various additives and electrolyte modifiers are used to expand the range of applications of AAO or to modify the anodizing process itself. One of the most common modifications of the electrolyte is the use of alcohols. Generally, for relatively high voltages (i.e., above 25 V for anodizing in sulfuric acid), much Joule’s heat is secreted

Fig. 4 (A) SEM, (B) HAADF-STEM, and (C–E) elemental distribution mapping images of aluminum, oxygen, and phosphorus in the porous alumina fabricated via phosphonic acid anodizing at 150 V. Reprinted with permission from Elsevier^[27]

Table 2 Novel electrolytes applied for the fabrication of AAO

Name	Operating conditions	Morphological features	Remarks	Reference
Citric acid	0.05% (up to 540 V), 0.5% (up to 425 V), 2% (up to 370 V), 4% (up to 300 V), 20°C	D_c range: 970–1420 nm	Relationship between the concentration of citric acid and the maximum voltage was found	[22]
Croconic acid	0.1 M, 293–323 K, 60 min, 5–40 A/m ²	—	Galvanostatic anodizing was employed	[23]
Etidronic acid	0.3 M, 145–295 V, 72 h, 293 K	D_c range: 530–670 nm	Stepwise voltage increase allowed to anodize aluminum at higher voltages; structural color generation occurs	[24]
Etidronic acid	0.3 M, 210–270 V, 16 h, 293–313 K	D_c range: 530–670 nm	Structural color generation was reported, and reflected light was in the range of 400–800 nm; the hexagonally arranged array was transferred to a mercapto-ester ultraviolet-curable polymer	[25]
Malic acid	0.5 M, 200–250 V, 293 K, 48 h	D_c range: 300–800 nm	At voltages above 250 V (up to 350 V), a black, burnt, nonporous oxide is formed	[26]
Phosphonic acid	0.5–2.0 M, 90–190 V (best arrangement in the range of: 150–180 V), 273–293 K, 14 h	D_c range: 370–440 nm	Maximum voltage at which nanoporous oxide is formed is limited by the concentration and temperature of the electrolyte; elemental mappings revealing the mechanism of anion incorporation into AAO were reported by the authors (Akiya et al.) (Fig. 3)	[27]
Phosphonoacetic acid	0.1–0.9 M, 205–245 V, 273–323 K, 3 h	D_c range: 500–550 nm	Structural color generation in the range of wavelength: 500–700 nm	[28]

Table 2 Novel electrolytes applied for the fabrication of AAO (*Continued*)

Name	Operating conditions	Morphological features	Remarks	Reference
Pyrophosphoric acid	74%–78%, 10–95 V, up to 72 h, 273–293 K	—	Alumina nanofibers were formed	[29]
Pyrophosphoric acid	74%–78%, 25–50 V, 9 min	37–75 nm spacing between the fibers	Hexagonally ordered alumina nanofibers were formed; for the first step of anodizing, 0.5 M H ₂ SO ₄ at 25 V and 0.3 M (COOH) ₂ at 50 V were used to provide high regularity of the concaves at the bottom of the pores	[30]
Pyrophosphoric acid	74%–78%, 268–313 K	6.9–9.1 nm of fibers diameter	Structural superhydrophilicity was obtained with a water wetting contact angle as low as 1°	[31]
Rhodizonic acid	0.1 M, 293 K, 60 min, 5–40 A/m ²	D_c range: 200–450 nm	Galvanostatic anodizing was employed	[23]
Selenic acid	0.1–3.0 M, 37–51 V, 273 K	D_c range: 95–110 nm (at 42–46 V)	In 3.0 M H ₂ SeO ₄ at a voltage range of 42–46 V, highly ordered AAO was obtained	[32]
Selenic acid	0.04–1.0 M, 5 mA/cm ² , 5°C, 1 h/10 min	Interpore distance vs. voltage relations: $D_c = 2.2U - 4.71$ Pore diameter vs. voltage relation: $D_p = 0.47U + 3.95$	Interpore distance and pore diameter increase linearly with selenic acid concentration increase	[33]
Selenic acid	3.0 M, 273 K, 46 V, 0–814 rpm	$D_c = 111$ nm	Defect density decreases with anodizing time; starting material with various purity levels was anodized; the influence of stirring rate was researched	[34]
Selenic acid	0.03–0.3 M, 273–293 K, 25–51 V, up to 3 h/1 h	Average pore diameter was 10.3 nm (48 V)	Nanoporous alumina with pore diameter below 10 nm was obtained	[35]
Squaric acid	0.1 M, 293 K, 100–120 V, up to 360 min	D_c range: 200–400 nm D_p below 100 nm	Up to 6 at.% of carbon was noticed in the formed oxide, due to the phenomenon of anion incorporation	[36]
Tartaric acid	0.4 M, 60 A/m ² , 18°C	$D_p = 110$ nm $D_c = 443$ nm	Incorporation of tartaric acid anions into AAO decreases the bandgap from 6.5 to 3.25 eV; after heat treatment at 500°C and 700°C increased to 3.35 and 3.5 eV, respectively	[37]
Tartaric acid	0.4 M, 18°C, 6 mA/cm ² , 70 min	$D_c = 443$ nm	The influence of the incorporation of tartarate anions on the optical properties of AAO was studied	[38]

on the anode, and the local temperature increase causes a locally enhanced electric field-assisted anodic dissolution of metal with vigorous oxygen evolution, which is commonly referred to in the literature as “burning.” The burning phenomenon disables successful anodizing. To prevent this, various alcohols are added to enhance the heat transfer and to make anodization at temperatures below the melting point of water possible. Zaraska et al. reported the fabrication of nanoporous AAO in phosphoric acid containing methanol or *n*-propanol at low temperatures, even at –5°C.^[13] It was found that the presence of

methanol decreases the interpore distance. Furthermore, the presence of both alcohols (25 vol.%) decreases current density and consequently, the oxide growth rate.

According to Qin et al., the influence of ethanol on the growth of anodic alumina is not monotonic.^[39] Up to 10 vol.% of ethanol, in sulfuric acid solution, increases current density and oxide growth rate; however, above this critical value, both decrease rapidly. It was reported that the more ethanol in the electrolyte, the wider the voltage range at which aluminum can be successfully anodized in sulfuric acid. In aqueous solution, the maximum voltage at

which aluminum can be anodized in sulfuric acid is 25 V (MA), whereas for the electrolyte with 50 vol.% of ethanol, a highly ordered AAO is formed at 30 V.^[39] For this reason, ethanol is also used for hard anodizing.^[20] According to Norek et al., a two-step anodizing process can be modified, using the hard anodizing approach in the first step (anodizing in oxalic acid) and mild anodizing in the second step, which significantly improved the arrangement of the nanoporous arrays.^[20] To widen the hard anodizing voltage range in the first step, ethanol was used, which permitted an increase in the interpore distance from the typical 250–300 nm up to 400 nm. Nevertheless, it was found that the ordering of AAO obtained by anodization in ethanol-containing electrolytes is worse in comparison with AAO formed in ethanol-free electrolytes.

Analogous results were reported for anodization performed in solutions containing EG. According to Song et al.,^[40] a galvanostatic anodization of aluminum in EG solution of oxalic acid or phosphoric acid strongly increases the required voltage. Thus, in a potentiostatic mode, at fixed voltage, the current densities would be much lower for processes performed in EG solutions. As in the case of anodizing in ethanol-modified H_2SO_4 solution, the addition of EG increases the voltage range for anodizing. According to Michalska-Domańska et al., the voltage range was expanded up to 35 V.^[41] Addition of EG into the electrolyte produces a highly ordered AAO with extremely small pores with a diameter of 14 nm and an interpore distance of 50 nm.^[42] In the case of an EG-modified electrolyte, a systemic study has shown that the greater the EG content, the lower the current density and consequently, the oxide growth rate. Templates with such ultra-small pores were used for the fabrication of Bi_2Te_3 and poly(3-hexylthiophene) (P3HT) nanowires. To obtain ultra-small nanopores, Ding et al. reported another approach: application of 1% of $\text{Al}_2(\text{SO}_4)_3$ and 1% of citric acid as additives to the electrolyte reduced the anodizing voltage to as low as 1 V, and consequently, an AAO with a diameter as small as 6 nm and an interpore distance as small as 20 nm was obtained.^[43]

Also the oxide growth rate can be tuned by the use of appropriate additives in the electrolyte. According to Salerno et al., addition of even 0.5 wt% of 1-butyl-3-methylimidazolium 2-(2-methoxyethoxy) ethyl sulfate and 1-butyl-3-methylimidazolium tetrafluoroborate (ionic liquids) increased the oxide growth rate in oxalic acid by a factor of 3.^[44,45] According to Le Coz et al.^[46] and Akiya et al.,^[27] during anodization, the electrolyte anions are incorporated into the pore walls. The process is hard to avoid and incorporated anionic species influence the AAO properties, as discussed previously for tartrates.^[37] This result led to the use of anionic additives that could be incorporated into the oxide and tune its properties. $[\text{Cu}(\text{EDTA})]^{2-}$ anions are stable in sulfuric acid and were used to incorporate copper into AAO.^[38] Only up to 0.24 at.% of Cu was found in the AAO; however, additional

photoluminescence (PL) bands in the UV–V is range that were attributed to the incorporated anions were noted.^[47] For the same reason, an organic dye, indigo carmine (IC) was also added to the sulfuric acid solution to grow an organic–inorganic hybrid material.^[48] AAO was found to contain over 2 at.% of nitrogen when anodized in 20 wt% H_2SO_4 with the addition of $5 \times 10^{-4} \text{ M}$ of IC. The AAO exhibited additional PL and Raman bands attributable to the incorporated organic anions, including those specific for the dye such as pyrrolidone ring bending and stretching (Raman spectroscopy).^[48]

Structural Color Generation

As discussed previously, anodization of aluminum allows the formation of oxide films with structurally generated color^[24,25,28] (Table 2). There are few mechanisms responsible for this color generation phenomenon. One of the most facile approaches for structural color generation was reported by Pashchanka et al.^[49] The structural color generation was based on the interference phenomenon of waves reflected from the aluminum–pore bottom interface and the metal layer sputtered on top of the pores. To achieve this, aluminum was anodized in 0.3 M $(\text{COOH})_2$ at 40 V for 6–12 min at the second step, and the thickness of the oxide formed ranged from 200 to 400 nm depending on the anodizing time. Next, an ultra-thin metallic layer (Al, Cr, Pt/Pd) was sputtered onto the surface of the AAO, and a wide range of the interference colors were obtained. Of course, the AAO layer must be treated as a mixture of Al_2O_3 and air (pores); thus, it exhibits its own specific refraction. However, due to the emptiness, it can be filled with other media and substituting of the air and changes the refraction. This concept is a foundation of the optical, real-time responding sensors reported by Wang et al.^[50] Filling the AAO with appropriate thickness with compounds such as *n*-hexane, EG, benzene, and CS_2 imparted an immediate optical response with a maximum peak at 618, 627, 641, and 673 nm compared to a maximum wavelength of 535 nm without this substitution, and the color change was visible even with naked eye.

Another bioinspired approach in structural color generation was reported by Kikuchi et al.^[24,25] (Table 2). Anodic alumina was obtained via anodization in etidronic acid; however, afterward, the formed oxide was selectively removed, and the remaining aluminum possessed surface periodic arrays of uniform nano-concaves. These concaves appeared as dimples on butterfly wings, and they reflected color from the visible range, depending on the angle of incident light (Fig. 5). A facile method of such pattern transfer onto a polymer surface has been developed.^[25] Therefore, any surface with this approach can be structurally colored.

A milestone in the structural color generation with the use of AAO was an application of pulse anodizing that allowed the formation of distributed Bragg reflectors

Fig. 5 (A) Bright structural colors obtained from the nanostructured aluminum specimen at different viewing angles. (B) Reflection spectrum of the nanostructured aluminum specimen at different angles under white light irradiation. (C) A schematic illustration of the reflection measurements obtained from the nanostructured aluminum specimen. Reprinted with permission from Elsevier^[24]

(DBRs).^[19,51] To obtain a 3D periodic structure along the pores, after MA provides an appropriate electric insulation of the sample, subsequent HA and MA,^[19] or high current and low current density^[51] pulses are applied, which provide high and low values of interpore distance and pore diameter along the pore depth, respectively. The periodicity of the morphological features of the pores provides periodicity of the effective refractive index of AAO, and the duration of the pulses controls the distance between the materials with varied refractive indices. Thus, the generation of the color, in this case, is based on the same interference phenomenon as reported by Pashchanka et al.^[49] However, in the case of DBR, not singular, but numerous (150 in the case of^[51]) color generation sites are present along the thickness, which enhances the reflected wave intensity. As an effect, the DBR approach provides much more intensive and vivid color (Fig. 6). As it is seen in Fig. 6, the longer low current density pulse (namely, T_p is the period between the end of n high current density peak and the end of $n + 1$ high current density peak), the longer the wavelength of the structurally generated color. The DBR approach is applicable to high-purity and technical purity aluminum making the approach attractive for industry because of the elimination of hexavalent chromium compounds essential in the dyeing process (Fig. 5).^[51] Due to the highly intensive and vivid color generation, AAO-based DBR was found to be a suitable optical sensing platform (compare to Ref. [50]). Application of reflectometric interference spectroscopy

(RIfS) allows to detect the presence of Hg^{2+} in water,^[52] vitamin C,^[53] and Au^{3+} .^[54]

3D Morphologies Formed via Aluminum Anodizing

In most cases, anodization of aluminum can be used for the formation of a hexagonally ordered array of parallel, quasi-uniform nanopores, perpendicular to the aluminum substrate (Figs. 2 and 7A,B). This is achieved by constant current (or constant voltage) anodizing. Various approaches to influence the morphology of the nanopores were discussed previously.^[51–54] Another approach based on the voltage change during anodization has been used for the formation of Y-shaped branched nanopores reported by Zaraska et al.^[55] (Fig. 7C,D). In this process, following the second step of anodization performed in 0.3 M $(\text{COOH})_2$ at 60 V, the voltage was decreased to 42 V, which yielded a decrease in the interpore distance and pore diameter. Finally, the voltage was decreased again to 30 V. In this way, in three-steps, Y-shaped nanopores were obtained. It is important to note that the pores in all of the zones were connected by the application of appropriate voltages. The subsequent voltage ratio was $\sqrt{2}$, which exhibits a positive impact on the morphology in terms of pore continuity. This process was used to obtain Y-shaped membranes and Y-shaped gold and polystyrene (PS) nanowires^[55] (Fig. 7D). Thus, such branched templates are demanded where the

formation of branched and simultaneously ordered nanostructures is required, like in various sophisticated junctions and circuits in micro and nano devices.

Nanoporous anodic alumina funnels (NAAF) can be obtained with the use cyclic anodization and pore widening in H_3PO_4 . After the second step of anodizing, the sample is chemically etched to widen the pores and then anodized again. This procedure can be cyclically repeated to form a nano-funnel architecture^[56,57] (Fig. 7F,G). With this approach, the pore diameter at the top is the widest one, and it is narrowest at the bottom. With the use of NAAF derived templates, a nano-conical array of copper nanostructures was formed via electrodeposition and used for efficient H_2O_2 electro-catalytic decomposition^[57] (Fig. 7H). Zaraska et al. reported the fabrication of inverted nano-funnels where instead of pore widening, subsequent anodization in various electrolytes is applied.^[58] For example, immediately after the second step of anodization performed in 0.3 M $(COOH)_2$ at 45 V, anodization at the same voltage, but in 0.3 M H_3PO_4 , is performed. In addition, the alternating use of the electrolytes i.e., after anodizing in H_3PO_4 , anodization is performed in $(COOH)_2$, then again

in H_3PO_4 and then again in $(COOH)_2$ which will produce periodic pore diameters.^[58] Another approach to form inverted NAAF (INAAF) is by annealing after anodizing^[59] (Fig. 7E). With this approach, instead of pore widening in H_3PO_4 as applied for NAAF,^[56,57] the sample is annealed at temperatures up to 600°C to provide immunity for chemical etching in the next step of anodizing (heat-treated alumina is much more immune to the reaction with acid than the as-prepared amorphous structure). Thus, a much lower reaction rate with the electrolyte in the top layer of AAO results in smaller pore diameter. If this methodology (anodizing with subsequent annealing) is repeated a number of times, an INAAF structure is obtained. Fabrication of NAAF and INAAF nanostructures may be beneficial in filtration, molecular sieving, and size-exclusion chromatography. Moreover, so-formed AAO templates may serve for fabrication of conical nanostructures made of other materials, providing high surface area, demanded in such applications as electrochemical sensing.

Santos et al. recently reported a totally new approach, sinusoidal pulse anodizing, where the current density

Fig. 7 (A) Top view and (B) cross section of AAO consisting of hexagonally ordered array of parallel, quasi-uniform nanopores, perpendicular to the aluminum substrate;^[125] Y-shaped branched nanopores (C) and Y-shaped branched PS nanowires formed in such template (D);^[55] INAAF (E)^[59] and nanoporous anodic alumina funnels (F–G);^[56,57] and copper nanocones formed in such AAO templates (H).^[57] Reprinted with permission from Elsevier^[56,57,125] and the Royal Society of Chemistry^[59]

changes continuously and periodically.^[60] This approach differs from previously reported pulse anodizing^[51–54] where only two values of current density (“low” and “high”) were used. Morphological features, such as pore diameter, also change continuously, depending on the current density. It was found that there are varying orders of maximum wavelength during light reflection (RfS) in such samples. The same sample may simultaneously exhibit a maximum reflection wavelength in the near infrared, visible, and ultraviolet range. With the change of the pore size, a refraction index changes and color is generated structurally. Moreover, introduction of various chemical inside the pores also changes the refraction index; thus, so-formed nanostructures are a promising optical sensing platform.

SELECTED APPLICATIONS OF ANODIC ALUMINUM OXIDE

Nanofabrication

Control of AAO morphology in the nanometer scale by varying operating conditions permits the use of this technology for numerous applications. Uniformity of pore diameter and interpore distance makes AAO templates attractive for nanofabrication.^[2] After the second step of anodization, highly ordered AAO is not ready for further processes to grow nanowires or NTs; therefore, numerous posttreatment approaches have been developed to eliminate the remaining, unoxidized aluminum and to open the pores at the bottom of the material to obtain a through-hole AAO template. First, the remaining metal must be removed by a selective redox reaction that is conducted with a saturated HgCl_2 aqueous solution,^[61] CuCl_2 in HCl ,^[62] CuSO_4 ,^[63] SnCl_4 ,^[64] or even Br_2 in CH_3OH .^[65] After aluminum removal, AAO is still closed at the bottom by the

barrier layer. The AAO is opened by using a 5% aqueous solution of H_3PO_4 ; however, optimization is very important because excessive processing would destroy the honeycomb structure due to the reaction of acid with the oxide.^[61] Such a through-hole membrane—AAO template—is ready to manipulate for further nanofabrication.

Nevertheless, application of a free-standing membrane in electrodeposition is used to grow metallic nanowires after additional posttreatment. According to Zaraska et al.,^[61] when an AAO membrane is used for Cu electrodeposition, Au must first be evaporated on the bottom side of the template, and then electrodeposition of thin Au layer is performed to provide electric contact at the bottom of each pore. As a result, a high filling ratio of the template and nanowires is achieved. For electrodeposition, it may also be used to obtain a ready-to-use template employing electrochemical barrier layer thinning (BLT). The BLT process is conducted at the end of the second step of the anodization and consists of a gradual, quasi-exponential voltage/current density decrease.^[66,67] Of course, there is a risk linked to the formation of thinner pores at the bottom, making the whole process less effective;^[68] therefore, the steady-state current density/voltage cannot be achieved by the system (stadium 4 in Fig. 3). With this approach, a hexagonally arranged AAO has opened pore bottoms and is placed on a conductive, metallic substrate, providing conductivity for electrodeposition.

Numerous review papers and book chapters utilizing AAO as a template for nanofabrication have been published. In this article, the review will focus on the most recently published achievements. Recently, AAO templates were used to fabricate nanowires of Ag,^[69–72] Ag–Au,^[71] Al,^[73] Au,^[55,71] Co,^[74,75] Co–Pd,^[76] Co–Pt,^[77] Co–Sm,^[78] Co–W,^[79] Cu,^[61] CuI,^[80] FeCoCu,^[81] InSb,^[82,83] Ni,^[68,71,84,85] NiGa,^[86] NiMn,^[87] P3HT,^[88] polyethylene-*b*-PS,^[89] polypyrrole (PPy),^[90,91] PS,^[55] Pt,^[92] Rh,^[93,94] Sb/Sb₂O₃,^[95]

SrFe₁₂O₁₉ (SrO·6Fe₂O₃),^[96] TiO₂,^[97] and even YBCO (YBa₂Cu₃O_{7-δ})^[98] (Table 3). Application of AAO templates permits the formation of high aspect ratio nanowires (Fig. 8). The morphological features of the obtained nanostructures are strictly linked to the AAO template geometry. Table 3 shows that metallic nanowire fabrication is most often performed by electrodeposition, which is facile and cost-efficient.^[55,61,68–72,74–79,81,84–87,92–95] Electrodeposition was also found to be suitable for the deposition of semiconducting InSb^[82,83] and TiO₂ from a novel TiOSO₄ bath.^[97] Moreover, electropolymerization is also used to form PPy nanowires.^[90,91] Sol-gel conducted in an AAO template was found to be suitable to obtain SrFe₁₂O₁₉^[96] and YBCO.^[98] Also melt injection and a template wetting method allowed the formation of nanowires made of CuI,^[80] (P3HT),^[88] polyethylene-*b*-PS,^[89] and PS^[55] due

to the nanometric size, catalytic properties,^[74,92,94] and changes in magnetic,^[75–79,81,86,87,96] plasmonic,^[73] electric,^[83] optical,^[80] or even superconducting^[98] properties, as well as enhancement in the performance of sensors^[69,72,90,91] or surface-enhanced Raman spectroscopy (SERS).^[70,84]

Application of AAO templates permits the form NTs by a diversity of techniques. Fabrication of NTs made of materials including Au,^[70] Au–Ni multisegments,^[99] multiwalled carbon NTs (MWCNTs),^[100,101] Fe,^[102] and Ni^[103,104] with the use of AAO templates has been reported (Table 4). Various methods such as electrodeposition^[70,99,102–104] and chemical vapor deposition (CVD)^[100,101] have been successfully applied. It should be noted that electrodeposition of materials in nanotubular form into an AAO template requires additional treatments, because alumina is an insulator. Lee et al.^[99] showed how to impart electric conductivity onto pore walls to make possible the electrochemical fabrication of NTs. A surface redox reaction was used to deposit a thin film of silver on AAO walls (14):^[99]

By alternating the deposition, segments of nickel and gold may be deposited as well.

NTs formed with the use of AAO templates are formed for magnetic,^[99,104] transport,^[100,101] and catalytic^[103] properties of nanostructures. Au NT arrays were also used as a high-surface area platform for SERS.^[70]

Anodic Aluminum Oxide-Based Sensors

The high surface area of AAO and its optical properties permitted the fabrication of two major groups of sensors: optical and electrochemical (Table 5). As discussed in “Structural Color Generation” and “3D Morphologies Formed via Aluminum Anodizing” sections, anodization of aluminum is used to generate structural colors, which is a foundation of optical sensing with the use of AAO. The color change in the presence of hydrocarbons and their derivatives is so distinct that real-time qualitative sensors can be fabricated.^[50] Furthermore, AAO-DBR may be used to detect Au³⁺,^[54,107] glucose,^[108] and Hg²⁺.^[52] To enhance sensitivity and improve the limit of detection (LOD), chemical functionalization of the pore walls is applied with H₂O₂ (to generate numerous surface –OH groups) and followed by the use of compounds such as 3-(mercaptopropyl)-trimethoxysilane (MPTMS)^[54] and APTES, (3-aminopropyl)trimethoxysilane.^[53] Such optical sensors exhibit superior performance and LOD harmful substances such as Hg²⁺ is as low as 200 ppb,^[52] even in tap water and river water samples.

Also, nanostructured materials formed with the use of AAO as the template are frequently used as sensors. In this case, usually electrochemical detection of the analyte with high-surface area electrode obtained via AAO templating

Table 3 Nanowires formed with the use of AAO as a template

Deposited material	Deposition method	Remarks	Reference
Ag	DC electrodeposition/28.7 g/dm ³ Ag ⁺ , −1.1 V, 10 min	Ag nanowires were applied as sensor for H ₂ O ₂ detection. Sensor was found to be free from interference originating from urea, glucose and ascorbic acid	[69]
Ag	Electrodeposition from AgNO ₃ solution	Ag nanowires (NWs) were used as SERS platform for Rhodamine 6G (R6G) detection	[70]
Ag	DC electrodeposition/commercial plating solution (Ag content 28.7 g/dm ³), $i = 1$ mA/cm ² , $t = 20$ min	Segment nanowires were formed, using AAO obtained via pulse anodization	[71]
Ag	DC electrodeposition/commercial plating solution (Ag content 28.7 g/dm ³), −1.1 V, 30 s	An electrochemical sensor based on Ag nanowires was assembled	[72]
Ag–Au	DC electrodeposition/20 mmol/dm ³ KAg(CN) ₂ + 10 mmol/dm ³ KAu(CN) ₂ , $i = 3$ –4 mA/cm ² , $t = 30$ min	Segment nanowires were formed, using AAO obtained via pulse anodization	[71]
Al	Anodization of imprinted Al	Plasmonic nanowires were obtained	[73]
Au	DC electrodeposition/commercial plating solution (Au content 7 g/dm ³), $i = 1$ mA/cm ²	A multistep anodization of aluminum allowed to form Y-shaped branched templates and consequently, Y-shaped branched nanowires	[55]
Au	DC electrodeposition/commercial plating solution (Au content 7 g/dm ³), $i = 5$ –7 mA/cm ² , $t = 30$ min	Segment nanowires were formed, using AAO obtained via pulse anodization	[71]
Co	DC electrodeposition/0.25 M Co(CH ₃ COO) ₂ , 0.44 M H ₃ BO ₃	Co nanowires were used as catalyst for methane decomposition	[74]
Co	Pulse electrodeposition/1.07 M CoSO ₄ , 0.19 M CoCl ₂ , 0.73 M H ₃ BO ₃ at a pH = 4, $I = 38$ mA/cm ² , 30 min	Magnetic properties of planar (2D) and 3D (deposited on anodized Al rod) arrays of Co NW were researched	[75]
Co–Pd	AC electrodeposition	Aqueous electrolytic baths with different proportions of CoCl ₂ and PdCl ₂ were applied; magnetic properties of nanowires were examined	[76]
Co–Pt	Pulse electrodeposition/0.485 M H ₃ BO ₃ , 0.3 M CoCl ₂ , 0.01 M K ₂ PtCl ₆ , pH = 4, −0.3 (18 s)/−1.0 (3–10 s)/0.0 V (5 s), 298 K	Multisegment nanowires consisting of Co–Pt and Pt layers were obtained; magnetic properties were researched	[77]
Co–Sm	DC electrodeposition/0.039 M SmCl ₃ + 0.046 M CoCl ₂ , 70°C, $j = 0.5$ –2.0 mA/cm ²	Various procedures of electrodeposition in nonaqueous solutions were tested; magnetic properties were investigated	[78]
Co–W	DC and pulse electrodeposition/0.2 M CoSO ₄ + 0.2 M Na ₂ WO ₄ + 0.04 M C ₆ H ₈ O ₇ + 0.25 M Na ₃ C ₆ H ₅ O ₇ + 0.65 M, H ₃ BO ₃ , pH = 5.0–8.0, $T = 20$ –60°C	A systemic study of the electrodeposition of Co–W into AAO template is presented; magnetic properties were examined	[79]
Cu	DC electrodeposition/0.5 M CuSO ₄ + 0.5 M H ₂ SO ₄ , 2 mA/cm ² , 30 min	High-surface area copper foils was covered by uniform nanowire arrays	[61]
CuI	CuI powder was melted and injected by pressure into AAO template	PL of CuI nanowire arrays was examined	[80]
FeCoCu	DC electrodeposition/35 g/dm ³ CoSO ₄ ·7H ₂ O, 2 g/dm ³ CuSO ₄ ·5H ₂ O, 15 g/dm ³ FeSO ₄ ·7H ₂ O, 10 g/dm ³ H ₃ BO ₃ , 10 g/dm ³ ascorbic acid, −1.8 V, 25°C, pH = 3	Fe ₂₈ Co ₆₇ Cu ₅ nanowires with modulated diameter were obtained in AAO templates formed by pulse anodization; magnetic properties were investigated	[81]

Table 3 Nanowires formed with the use of AAO as a template (*Continued*)

Deposited material	Deposition method	Remarks	Reference
InSb	DC and pulse electrodeposition	Various experimental procedures were applied to obtain InSb nanowires	[82]
InSb	Pulse electrodeposition/0.06 M InCl_3 , 0.045 M $\text{SbCl}_3 \cdot 3\text{H}_2\text{O}$, 0.2 M citric acid, 0.15 M sodium citrate from -2.3 to -1.5 V (1 ms)/ -0.5 to 0 V (5 ms), 293 K	The influence of annealing on the electric properties of InSb nanowires was researched	[83]
Ni	Pulse electrodeposition/200 g/L $\text{NiCl}_2 \cdot \text{H}_2\text{O}$, 120 g/L $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$, 50 g/L H_3BO_3 , 5.67 mA/cm ² (1 s)/0 (1 s)	Various electrochemical BLT procedures were tested for successful Ni NW nanofabrication	[68]
Ni	DC electrodeposition/0.35 mol/dm ³ NiSO_4 , $i = 3\text{--}5$ mA/cm ² , $t = 30$ min	Segment nanowires were formed, using AAO obtained via pulse anodization	[71]
Ni	DC electrodeposition/30 wt% NiSO_4 , 4.5 wt%, H_3BO_3 , 4 V, 55°C, 1 h	The Ni NW were used as SERS platform for R6G detection	[84]
Ni	DC and pulse electrodeposition/0.01 M $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$, 0.05 M K_2SO_4 , 0.1 M H_3BO_3	Various experimental approaches were tested to obtain classical 2D array of Ni NW and 3D Ni NW array, where the nanowires were interconnected	[85]
NiGa	DC electrodeposition	Various electrodeposition bath compositions and current densities were investigated; magnetic hysteresis loops were taken	[86]
NiMn	DC electrodeposition	Various electrodeposition bath compositions and current densities were investigated; magnetic hysteresis loops were taken	[87]
P3HT	Spin coating of P3HT in CH_3Cl on AAO template followed by annealing at 250°C for 30 min	Asymmetrically ordered arrays of P3HT nanowires were obtained	[88]
Polyethylene- <i>b</i> -PS	Solid polymer was put onto AAO at 170°C and then annealed at 180°C in N_2 atmosphere for 5 h	Thermal properties of polymer NWs were examined	[89]
PPy	Potentiostatic electropolymerization/0.05 M pyrrole + 0.05 M potassium hydroquinone monosulfonate + 0.1 M NaClO_4 , 0.1 M LiClO_4 , or 0.1 M citric acid (basic electrolyte), 1.5 V, 100 s	PPy and hydroquinone monosulfonate-doped PPy NWs were examined as pH sensors	[90]
PPy	DC electrodeposition/0.4 M HNO_3 , 0.5 M NaNO_3 , 0.2 M pyrrole, 0.1 M AgNO_3 , -0.65 V, 100 s, RT	PPy with incorporated Ag nanoparticles was tested as H_2O_2 sensor	[91]
PS	Immersion of AAO template in 1.5 wt% solution of PS in chloroform	A multistep anodization of aluminum allowed to form Y-shaped branched templates and consequently, Y-shaped branched nanowires	[55]
Pt	DC electrodeposition	Various approaches were tested; Pt NWs were used for methanol decomposition (electro-oxidation)	[92]
Rh	DC electrodeposition/from -400 to -75 mV, commercial Rh deposition bath, RT	Various approaches were tested	[93]
Rh	DC electrodeposition/0.01 M Na_3RhCl_6 + 0.5M NaCl, -0.3 V, RT	Rh NWs were tested as catalysts for electro-oxidation of nitrates in aggressive medium	[94]
Sb/Sb ₂ O ₃	DC electrodeposition/30 g/L $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$, 1.8 g/L SbCl_3 , 115 g/L $\text{Na}_4\text{P}_2\text{O}_7 \cdot 10\text{H}_2\text{O}$, 7 g/L tartaric acid, 0.4 g/L gelatin, 0.5 to 2 mA/cm ²	Various procedures were tested to achieve Sb and Sb/Sb ₂ O ₃ nanowires arrays in AAO with various morphology	[95]

(Continued)

Table 3 Nanowires formed with the use of AAO as a template (*Continued*)

Deposited material	Deposition method	Remarks	Reference
SrFe ₁₂ O ₁₉ (SrO·6Fe ₂ O ₃)	Sol-gel	Magnetic properties of nanowires with varied morphology were investigated	[96]
TiO ₂	DC electrodeposition/0.3 mL H ₂ O ₂ , 0.088 g TiOSO ₄ ·H ₂ O, 0.28 g of KNO ₃ in 55 mL of water, 10°C, pH = 3	TiOSO ₄ precursor was used for the first time for electrodeposition of TiO ₂ in the form of nanowires	[97]
YBCO (YBa ₂ Cu ₃ O _{7-δ})	Sol-gel	Morphology, crystal structure, and superconducting properties of YBCO NW were investigated	[98]

Table 4 NTs formed with the use of AAO as a template

Deposited material	Deposition method	Remarks	Reference
Au	Electrodeposition from HAuCl ₄ solution	The Au NT were used as SERS platform for R6G detection	[70]
Au-Ni	DC electrodeposition/ Au: commercial plating solution Auruna 5000 at 2.2–2.5 mA/cm ² ; Ni: 0.0841 mol/L NiCl ₂ ·6H ₂ O, 1.59 mol/L Ni(H ₂ NSO ₃) ₂ ·4H ₂ O, 0.33 mol/L H ₃ BO ₃ at 2.4 A/cm ²	Multi-segment Au–Ni–Au–Ni NTs were formed in AAO after BLT and redox Surface reaction providing electric conductivity of the pore walls; magnetic properties of the NTs were investigated	[99]
Carbon NTs (CNTs)	Catalyst free CVD into AAO membrane; toluene and ethanol were used as carbon precursors; 850°C, Ar atmosphere	CNTs were functionalized with H ₂ O ₂ to get carbonyl and carboxyl groups; molecular transport through AAO-CNT functionalized membrane was studied	[100]
Carbon NTs (CNTs)	Catalyst free CVD into AAO membrane; toluene and ethanol were used as carbon precursors; 850°C, Ar atmosphere	MWCNTs were functionalized with H ₂ O ₂ to get carbonyl and carboxyl groups; electrochemical properties of the AAO-MWCNT composite and ionic conductivity were researched	[101]
Fe	DC electrodeposition/120 g/L FeSO ₄ ·7H ₂ O, 45 g/L H ₃ BO ₃ , 1.35 V, 50°C	Structure and morphology of Fe NTs were researched	[102]
Ni	DC electrodeposition/1.4 M Ni(NH ₂ SO ₃) ₂ ·4H ₂ O, 0.5 M H ₃ BO ₃ , 10 mA/cm ² , pH = 3.5	Ni NTs were researched as a catalyst for hydrogen generation	[103]
Ni	DC electrodeposition/100 g/L NiSO ₄ ·6H ₂ O, 30 g/L NiCl ₂ ·6H ₂ O, 40 g/L H ₃ BO ₃ , 1.4 V, pH = 2.5	Morphology, structure and magnetic properties of nickel NT were tested	[104]

Table 5 Anodic alumina based sensors

Sensing materials	Detected compound/type of detection	LOD (mol/dm ³)	Remarks	Reference
AAO	Benzene/optical	The authors focused on the phenomenon of structural color generation and its change according to the used chemicals. Qualitative, real-time responding sensors have been assembled		[50]
	CS ₂ /optical			
	EG/optical			
	<i>n</i> -Hexane/optical			
AAO	H ₂ O (humidity)/electric	—	Application of capacitance-based method allowed to use AAO as humidity sensor in the range of 15%–80%	[105]
AAO	H ₂ O (humidity)/electric	—	A facile method of fabrication of AAO humidity sensor on paper was reported	[106]
AAO-DBR	Au ³⁺ /optical	1.56 × 10 ⁻⁷ (30.7 ppb)	The AAO-DBR was functionalized with MPTMS (3-(mercaptopropyl)-trimethoxysilane) to achieve superior sensing performance	[54]
AAO-DBR	Au ³⁺ /optical	10 ⁻⁷	No significant interference neither from Fe ³⁺ , Mg ²⁺ , Co ²⁺ , Cu ²⁺ , Ni ²⁺ , Ag ⁺ , and Pb ²⁺ , nor from tap water was noticed	[107]
AAO-DBR	Glucose/optical	1.80 ppm	Efficient, real-time biosensors were assembled	[108]
AAO-DBR	Hg ²⁺ /optical	10 ⁻⁶ (200 ppb)	AAO-DBR MPTMS functionalized sensors allowed to detect Hg ²⁺ in the presence of interference cations (Co ²⁺ , Mg ²⁺ , Ni ²⁺ , Cu ²⁺ , Pb ²⁺ , Fe ³⁺ , Ca ²⁺ , Cr ⁶⁺ , and Ag ⁺), tap water, and river water	[52]
AAO-DBR	Vitamin C/optical	2 × 10 ⁻⁸	AAO-DBRs were functionalized with APTES to obtain high-performance sensor	[53]
Ag Nanowires	H ₂ O ₂ /electrochemical	5 × 10 ⁻⁴	Ag NW sensors are free from ascorbic acid, uric acid, and glucose interference	[69]
Ag Nanowires	H ₂ O ₂ /electrochemical	2.92 × 10 ⁻⁵	Long-term stability of sensors (42 days)	[72]
Au nanoporous films	Epinephrine/electrochemical	2.42 × 10 ⁻⁶	The sensors was assembled by Au sputtering of Au on AAO template and subsequent Au electrodeposition	[109]
Cu nanocones	H ₂ O ₂ /electrochemical	1.8 × 10 ⁻⁴	Copper nanocones were formed in cyclically anodized and chemically etched AAO	[57]
PPy	pH/electrochemical	—	High sensitivity in the pH range of 2–12	[90]
PPy with incorporated Ag nanoparticles	H ₂ O ₂ /electrochemical	4 × 10 ⁻⁴	PPy–Ag NP composite had the best performance after annealing	[91]

is the key. For example, H₂O₂ can be detected with Ag nanowires,^[69,72] Cu nanocones,^[57] and PPy nanowires^[91] with the lowest LOD being 2.92 × 10⁻⁵ M.^[72] Wierzbicka and Sulka reported a facile epinephrine sensor fabrication method;^[109] on an as-obtained AAO where a thin layer of Au was sputtered followed by Au electrodeposition to produce a high-surface area nanoporous Au film, which, when used as a sensor, exhibited a LOD equal to 2.42 · 10⁻⁶ M. Thus, sensing with AAO as key material allows the

detection of various substances. Impressive LODs using these sensor assemblies make this material attractive for industrial applications.

Other Emerging Applications of Anodic Aluminum Oxide

One of the first functional applications of AAO was filtration. Thus, the geometry of AAO and its application as

a filtering material were fundamental to its application in dialysis. According to Attaluri et al.,^[110] AAO was able to filter such compounds as creatinine, vancomycin, and inulin. Due to the high aspect ratio, AAO was also used as a drug-releasing platform. High diameter-to-length ratio permits the timed release of medicinal molecules such as 2-deoxyadenosine^[111] or ibuprofen.^[112] Moreover, according to the feasibility of the anodizing technique, even elements with curved surfaces, such as stents,^[111] were subjected to anodic oxidation to release medicines including 2-deoxyadenosine up to 140 h.^[111] Wang et al.^[113] reported fabrication of AAO-based nanocapsules, loaded with the anticancer drug, Apo2L/TRAIL, leading cancer cells to apoptosis. The loading capacity of AAO nano-capsules equaled 104 ± 14 $\mu\text{g}/\text{mg}$. The surface area of AAO was used to culture cells including hepatic cells^[114] and osteoblasts;^[115,116] however, anodic aluminum itself causes strong inflammatory reaction so that it can only be used for *in vitro* cell culturing. Karlsson et al. reported the strong oxygen-free radical generation while leucocytes were cultured on AAO.^[117] Furthermore, *in vivo* research on mice showed that the application of AAO caused chronic inflammatory response of the organism and induced activation of macrophages and pro-inflammatory cytokines around the alumina.^[118]

The high surface area of AAO suggested applications in renewable energy harvesting and storage. For example, Wiedemann et al. report the application of AAO in polymer solar cell fabrication. AAO was used to form nanowires of P3HT, and subsequent deposition onto the nanowires a layer of 6,6-phenyl-C61-butyric acid methyl ester to obtain a developed interface between an electron donor and an acceptor,^[119] which improved the performance of the cell (increased fill factor, photocurrent density, and power conversion efficiency). Kim et al. also reported the fabrication of polymer solar cells with P3HT and C_{60} as the electron donor and the acceptor, respectively.^[120] They found that application of AAO for the interface enlargement increased the photocurrent four times, the fill factor from 0.31 to 0.46, and power conversion efficiency 6.6 times. A development of the surface area led to research on the electrodes for lithium-ion batteries. According to Cheah et al., atomic layer deposition (ALD) was used to transfer the pattern of AAO to TiO_2 .^[121] The subsequent TiO_2 nanowires possessed a 10 times greater capacity than planar titania films and were maintained for 50 cycles. ALD of V_2O_5 into AAO produced electrode material with a capacity equal to 142 mAh/g, which is close to the theoretical value (147 mAh/g).^[122]

As discussed previously, the morphology of AAO influences the wetting contact angle. According to Kikuchi et al.,^[31] alumina nanowires grown by self-organized anodizing in pyrophosphoric acid provided a water wetting contact angle as small as 1° , which indicates superhydrophilicity. On the other hand, due to the AAO nanoporous morphology, the contact angle may be as high as 127.5° .^[123]

According to Norek and Krasinski, after chemical bonding of perfluorooctyltrichlorosilane to AAO, even the wetting contact angles as high as 150.7° were achieved (superhydrophobicity).^[124]

CONCLUSION

AAO is an attractive nanomaterial due to the ease of morphology control in the nanometric scale. Currently, numerous reports on new fabrication methods, including anodizing in novel electrolytes (which allow the generation of structural colors or tuning of optical properties such as bandgap), anodizing in electrolytes with various additives to obtain ultra-small pores, ultra-fast growth of the oxide, or the addition of new properties to AAO, or anodizing with alternating voltage or current density to obtain 3D geometry. Moreover, AAO templates are frequently used for the fabrication of hexagonally arranged arrays of nanowires and NTs made of metals, polymers, semiconductors, or even superconductors to change or enhance sensing, magnetic, optical, electric, or catalytic properties. Furthermore, both nanofabrication and 3D AAO nanostructuring allow the assembly of sensors with outstanding properties: insignificant influence of the presence of interference with simultaneous LODs of substances such as glucose, mercury cations (even in with samples taken from the river), or hydrogen peroxide. AAO nanostructures are being also used in different fields including renewable energy harvesting and storage, or cancer cell treatment.

Arc-Welding: Lithium-Containing Aluminum Alloys

V. I. Ryazantsev and V. A. Fedoseev

Research Institute of Aviation Technology, Moscow, Russia

Abstract

The development of structures in the aerospace industry is associated mainly with the application of advanced methods and new technologies. Promising metals include alloys containing lithium (the lightest metal, its density is 543 kg/m^3). The use of these alloys in welded structures reduces the weight by 20–25% in comparison with structures produced using conventional aluminium alloys such as D16, V95, etc. This article shows that alloys of aluminium with lithium of all alloying systems have metallurgical and technological special features which must be taken into account when producing welded sections by fusion welding.

Keywords: Anisotropy; Fillers; Fusion zone; Oxidizability; Pore formation; Stress concentrators.

The development of structures in the aerospace industry is associated mainly with the application of advanced methods and new technologies. Promising metals include alloys containing lithium (the lightest metal, its density is 543 kg/m^3). The technology of producing these alloys as well as of producing sections and systems from them is new and requires extensive investigations and tests, and production testpieces.

Aluminium alloys with lithium of the following alloying systems have been developed and are used on an increasing scale: Al-Mg-Li (1420, 1421 and others), Al-Cu-Li (1450, 1460 and others), Al-Li-Cu-Mg (1430, 1440, 1470 and others), Al-Cu-Zn-Li (1464 and others) (Table 1).^[1,2] The use of these alloys in welded structures reduces the weight by 20–25% in comparison with structures produced by reverting to conventional aluminium alloys such as D16, V95, etc.

Alloys of aluminium with lithium of all alloying systems have metallurgical and technological special features which must be taken into account when producing welded sections by fusion welding:

1. Sensitivity to stress concentration. For this reason, the individual elements of welded components should not contain stress concentrators, and the welded joints should be displaced from the zone of bending stresses and gradients of stiffness.
2. High anisotropy of the properties of pressed and stamped semi-finished products; welded joints should not be produced in the height direction when arc-welding semi-finished products with the weld distributed along the height of the fibre. The tensile strength of the welded joints decreases by 20–40% and the bending angle by 40–80% in comparison

with the same characteristics of joints produced in specimens with the fibres in the longitudinal direction.

3. Increased oxidisability of heated surfaces of the alloys during their interaction with air in the course of welding. It is therefore necessary to ensure efficient shielding of molten metal of the molten pool and heat affected zone by inert gases, both from the convex side of the welded joint and the weld root.
4. Semi-finished products made of these alloys (stampings, forgings, pressed strips, pressed sections, pressed bars) have higher sensitivity to the thermal cycle of welding. Clusters of microcavities and microcracks may form in the fusion zone of the welded joint (especially in manual multi-pass welding and backing runs), which greatly reduce the properties of welded joints. It is therefore more efficient to use single pass welding and reduce the volume of manual welding.
5. All semi-finished products of these alloys have increased susceptibility to pore formation in welding. This is associated with the special features of the structure of oxide films and the presence of a subsurface layer with different compounds of lithium. To produce welded joints without pores, it is necessary to use special technological procedures.
6. All semi-finished products in aluminium alloys with lithium greatly differ from other conventional aluminium alloys by their thermo-physical properties, namely the thermal conductivity coefficient is 1.3–1.8 times lower and the specific electrical resistivity is 1.4–2 times higher than those of D16, V95, 1201 and other alloys. Therefore, the welding conditions differ from those used previously.

Table 1

Alloy	Content, % (base-Al)					
	Mg	Li	Cu	Ti	Zr	Sc
1420	5.45	2.1	–	–	0.1	–
1421	5.0	1.9	–	–	0.08	0.17
1423			–		0.07	0.1
1440	0.8	2.0	1.7	0.08	0.15	–
1450	–	1.9	3.1	–	0.1	–
1460	–	2.1	3.1	0.12	0.09	0.08
1470	1.55	2.5	0.5	–	0.09	2

Note: Mean nominal composition is given.

Experimental results show^[3] that to produce welded semi-finished products in aluminium alloys with lithium, it is necessary to use only ingots produced by melting in vacuum-induction furnaces followed by holding in a vacuum mixer and pouring in inert gases (the so-called fluxless melting technology). Semi-finished products from aluminium alloys with lithium produced by fluxless technology have satisfactory weldability by arc-welding.^[3–5]

When arc-welding aluminium alloys with lithium and when tack welding and producing backing runs, it is recommended to use filler wires (Table 2) whose chemical composition differs from that of the parent metal. Arc-welding in inert gases without filler wire is not recommended because of the high hot cracking susceptibility and reduced ductility properties of the welded joints.

Additional requirements are imposed on the design of welded sections and systems made of aluminium alloys with lithium.

Only butt welded joints should be used. It is not recommended to use T, fillet or lap joints. The surface of welded components and blanks (flanges, nozzles, etc) should have the roughness parameter $Ra \leq 6.3 \mu\text{m}$. In a section with a width of $\geq 15 \text{ mm}$ from the joint edge, it is necessary to develop special design forms with minimum concentrators, especially smooth transitions in areas of changes in the cross section of components, reduction of eccentricity, etc.

To increase the cyclic strength of welded joints, it is necessary to provide facilities for removing the weld penetration and the welded joints should be made in the

Table 2

Alloy	Filler wire
1420	Sv-AMg63
1421	Sv-AMg63
1423	Sv-AMg63
1440	Sv-1217
1450	Sv-1217
1460	Sv-1217
1470	Sv-1177
1430	Sv-1177

direction normal to the rolling direction (welded joints made along the welding direction are also permitted). It is recommended to use panel-type structures which enable welding to be carried out with continuous penetration using mechanisms for stretching joints and, correspondingly, with minimum deformation under residual stresses. It is not recommended to use pressed strips or forgings.

Welded sections and systems in aluminium alloys with lithium can be produced by three methods: I) fabrication of blanks; shaping; straightening; quenching; sizing; artificial ageing; chemical milling or mechanical removal of the surface layer; welding the section; straightening; quality inspection; II) fabrication of blanks; shaping; straightening; chemical milling or mechanical removal of the surface layer; welding the section; thermal straightening in a jig (thermal fixation) combined with quenching; straightening; artificial ageing; quality inspection; III) fabrication of blanks; shaping; straightening; quenching; straightening; chemical milling or mechanical removal of the surface layer; welding of the section; thermal straightening in a jig (thermal fixation) combined with artificial ageing; dressing; quality inspection.

The second method of producing welded sections enables the efficiency of welded structures to be increased by removing residual welding stresses, and increasing the corrosion resistance and mechanical properties of welded joints.

The selection of methods of welding sections and systems of aluminium alloys containing lithium is determined by the structure and properties of oxide films on the surface, the thickness and geometry of the welded joint, the conditions and quality of assembly for welding, as well as requirements on the leak tightness of welded joints.

For all semi-finished products made of aluminium alloys with lithium, it is recommended to use AC welding in argon or in a mixture of argon and helium because of the special features of the structure of the oxide films on the surface. In DC welding with straight polarity in argon or helium, the quality of formation of the welded joint is not satisfactory.

To produce high-quality welded joints in alloys of aluminium with lithium, it is necessary to use a special method of preparing the surface of blanks for welding.^[3,4] As a result of the special features of interaction of lithium with the atmosphere in heating,^[3–5] to obtain welded joints without pores it is necessary to use one of the two methods of surface preparation: removal of the surface layer or thermal vacuum treatment.^[6]

Removal of the surface layer to a depth of 0.05–0.2 mm, depending on the conditions of heating, should be carried out by mechanical or chemical methods from the ends and the top and lower sides of every welded component at a distance of $\geq 15 \text{ mm}$ from the joint line. The amount of surface layer removed is determined by the temperature of heating the semi-finished products in rolling, pressing, forging,

Table 3

Alloy	Recommended thickness of removal of the surface layer, mm, at temperature of, °C					
	400	420	450	470	500	520
1420	0.06	0.12	0.15	0.2	—	—
1421	0.06	0.12	0.15	0.2	—	—
1423	0.06	0.12	0.15	0.2	—	—
1440	0.03	0.05	0.1	0.15	0.2	0.2
1450	0.03	0.05	0.1	0.15	0.2	0.2
1460	0.03	0.05	0.1	0.15	0.2	0.2
1430	0.05	0.1	0.15	0.2	—	—
1470	0.05	0.1	0.15	0.2	—	—

Note: For all alloys at 120°C it is recommended that the thickness of the removal layer should be 0.01 mm.

stamping as well as by the temperature of final quenching prior to welding (Table 3). If the heating temperature and time of the semi-finished products for quenching are not known, it is necessary to remove a surface layer ≥ 0.2 mm thick. A surface layer 0.05–0.2 mm thick should be removed on blanks subjected to final heat treatment. Heating of components after removing the surface is not permitted. In repeated heat treatment at a temperature of $>400^\circ\text{C}$ (after inspecting the layer), it is necessary to remove again the surface layer to a depth of 0.06–0.08 mm. In repeated heat treatment at a temperature of $\leq 150^\circ\text{C}$ after carrying out controlled removal, only mechanical scraping or chemical etching should be carried out.

In drawings for the initial blanks, it is necessary to take into account a technological allowance of 0.05–0.2 mm (depending on the temperature to which the material is heated in heat treatment) per side.

For 1420, 1421, 1423 and 1430 alloys, thermal vacuum treatment should be carried out at a temperature of $470 \pm 5^\circ\text{C}$ for 2 hr irrespective of the thickness of the joints, for 1440, 1450 and 1460 alloys at $530 \pm 5^\circ\text{C}$ for 2 hr.

Prior to thermal vacuum treatment, the components should be degreased and subjected to chemical pickling with clarification in a hydrochloric acid solution under the conditions described in Ref. [7]. Thermal vacuum treatment is carried out in vacuum furnaces in which a vacuum of ≤ 0.13 Pa can be obtained at the isothermal holding temperature (for example, in SNV-95–30/7.5 or SKV-5–15–5/9 furnaces).

Sheets and blanks should be suspended in the heating chambers of vacuum furnaces, with a gap of ≥ 25 mm. Cooling of the charge after completing holding is carried out in vacuum to a temperature of $\leq 150^\circ\text{C}$.

Shortly prior to welding, it is necessary to clean all surfaces of the joint with a scraper, irrespective of the surface preparation method. The width of the cleaned zone in relation to the thickness of components is 10–15 mm. Surface preparation of the welding wire for welding should be carried out only by the chemical method.

The etching, degreasing and polishing conditions are given in Ref. [7]. The permissible storage time of the components with the surface layer removed to a depth of 0.05–0.2 mm (mechanically or by chemical methods) prior to welding should be no more than 3 months.

The permitted storage time of the components after vacuum treatment prior to welding is no longer than 12 months. The components should be stored in a dry, heated area at a temperature of $\geq 15^\circ\text{C}$ and a relative humidity of $\leq 80\%$. The storage time of the components cleaned with a scraper prior to welding should not be longer than 5 hr. The storage time of filler wire after chemical polishing is 16 hr in an open cartridge, 38 hr in a polyethylene bag and 120 hr in a hermetic box in inert gases.

High-quality welded joints can be obtained only if the requirements on the process of assembly for welding are strictly adhered to. In assembly, it is necessary to ensure that the weld edges are tightly pressed to the welding backing strip and the contour and nominal length of the blanks along the end are not affected. Prior to clamping with a pneumatic or some other special device (i.e. in the free state), it is permitted to have only local gaps in any area of the contour with a size of $\leq 0.3\delta$ over a length of no more than 200 mm or $\leq 0.5\delta$ along the entire length of the contour (δ is the thickness of the material in the joint). In assembly it is essential to combine the end of the weld edges with the axis of the welding backing strip by placing the blank on base holes and by ensuring accurate machining of the edges (milling, shaving, turning, etc). For example, for components with a thickness of 0.8–2.0, 2.1–4.0 and 4.1–6.0 mm, the permissible deviation from the axis of the welding backing strip is ± 0.25 mm, ± 0.35 mm and ± 0.5 mm, respectively. The permissible deviation of the electrode axis from the axis of the joint is no greater than ± 0.5 mm. Displacement (distortion) of the edges prior to welding should not exceed 10% of the thickness of the material.

In assembly the gap in the joint between the edges of the components should be 0–0.5 mm (for a thickness of 1–3 mm) and 0–0.7 mm (for a thickness of 4–6 mm). In welding with a rotating electrode, the permissible gap in the joint can be increased 1.5–2.5 times.

To improve the quality of welded joints in lithium-containing aluminium alloys, reduce the number of defects, improve the quality of formation of the penetration area, especially when welding without a backing strip, and reduce the consumption of expensive argon in blowing, it is recommended to use TFA-5, TFA-9 and TFA-15 fluxes. The latter represent a melted mixture of components such as CaF_2 , BaF_2 , MgF_2 , LiF , HCl , AlF_3 , and BaCl_2 , which should be stored in a hermetic sealed glass or plastic box for one year. Prior to welding, the melted mixture of the components is diluted with a 4–5% alcohol solution at a ratio of 1:1. The storage time of the alcohol suspension of the flux is not longer than 25 times. Prior to deposition, it is mixed until a homogeneous mass

is obtained and then deposited on the reverse side of the joint using a brush at a width of 5–10 mm from the joint. The flux must not be deposited on the ends of the weld edges. The break between flux deposition and the start of welding should not be longer than 8 hr. The conditions of manual and automatic welding components with fluxes do not differ from those in welding without the flux. The remnants of the flux should be removed from the welded components not later than 8 hr after welding. This should be carried out by rinsing in warm water (≥ 40 – 50°C) using brushes.

Fluxes make it possible to reduce the extent of removal of the surface of the metal to 0.05–0.08 mm (instead of 0.15–0.2 mm). This greatly increases the coefficient of utilisation of the metal. The best results are obtained using TFA-15 flux (Table 4). In welding without a backing strip with fluxes, the penetration area is characterised by a smooth transition to the parent metal surface. The number of cycles to fracture in low-cycle tests of the specimens welded with fluxes is 1.5–2.2 times greater than without the flux.

To improve the quality of welded joints in aluminium alloys containing lithium, taking into account the need to change frequently production programmes and stringent requirements on assembly for welding, it is recommended to use flexible production systems (FPS) with rapid readjustment for the production of components of any range in the given ranges of their characteristics.^[8] Processing equipment included in the composition of the FPS is highly aggregated and consists of individual aggregates (construction modules). In the process of development of the FPS, it is necessary to improve functional units, dryers and control systems, whereas the main metallic frame (guiding beams, trucks, etc) remain unchanged.

The FPS based on the UPSF complex with digital programme control have been developed for producing sections and systems for arc welding. All components of the system based on the UPSF machine-jig-tool-component are closely linked in a single system to ensure the required accuracy of all operations carried out in accordance with the programme.

A dimensional-parametric series of UPSF equipment: UPSF-2, UPSF-2–1, UPSF-2–2, UPSF-3–1, UPSF-3–2, UPSF-4, has been developed to include the entire range of components.^[8,9] These systems make it possible to carry out in the same working area operations of machining weld edges, surface preparation for welding and welding of joints of any spatial form, in accordance with agreed programmes. This greatly increases the accuracy of assembly for welding. This is especially important for lithium-containing aluminium alloys. When using type UPSF equipment, the assembly-welding jig becomes an element of the machine-device-tool-component system, and is subject to special requirements to ensure procedure and combined operation of all functional aggregates of the system.

The use of type UPSF equipment in a complex with specialised jiggings makes it possible to use completely new methods of securing the weld edges to the backing strip, namely the moving roller clamp and a power guide. The former, moving together with the welding torch, greatly simplifies and reduces the weight of the constructions of assembly and welding equipment, and ensures uniform and stable clamping in the welding zone along the entire length of joints of any spatial form.^[8,9]

To increase the accuracy of the contour of components and reduce the labour content of preparatory operations prior to welding (positioning, assembly and welding equipment, writing programmes for numerical remote control), the surface of the welding backing strips should be machined (milled) in UPSF equipment using the programme of the theoretical contour of the component. To ensure high and stable quality of the welded joints, production areas of welding shops and sections should have constant temperature and moisture content and dust contamination parameters.

When welding lithium-containing aluminium alloys, the moisture content should be maintained at 40–75%, the temperature at 18– 30°C and the dust content at $\leq 0.5 \text{ mg/m}^3$. Movement of air masses in the assembly-welding shop should not exceed 0.5 m/sec, in welding areas not more than 0.3 m/sec. Purified air should be supplied from outside the zone of the welding equipment from special stations.

Table 4

Thickness of removed surface layer, mm	Presence of pores on radiographs of welded joints produced using a flux					
	No flux	TFA-5	TFA-9	TFA-9 A	TFA-15	FA-IT
0	Yes	Yes	Yes	Yes	Yes	Yes
0.02	Yes	Yes	Yes	Yes	Yes	Yes
0.05	Yes	Yes	Yes	Yes	Yes	Yes
0.08	Yes	Yes	Yes	Yes	No	Yes
0.1	Yes	Yes	No	No	No	Yes
0.12	Yes	Yes	No	No	No	Yes
0.15	No	No	No	No	No	No
0.2	No	No	No	No	No	No

During electric welding operations, new previously not examined factors have been observed, in relation to the well-known detrimental and harmful production factors (increased brightness of light, electric circuit voltage, increased temperature, etc). This is associated with the fact that lithium belongs to the group of alkaline metals with high chemical activity. It has a distinctive irritating and generally toxic effect. When assembly and welding operations are carried out, lithium and its compounds can be found in the air of the working zone and in the form of condensation aerosol and disintegration aerosol. The former may be found in the air of the working zone in manual or automatic welding, while the latter forms in cutting and machining as well as in cleaning welds with a metallic brush. The maximum permissible concentration of the condensation aerosol of lithium is 0.02 mg/m^3 , that of the disintegration aerosol 0.5 mg/m^3 . The working zones and the welding equipment and areas where technological operations are carried out (scraping, cleaning with a brush, etc) and where lithium and its compounds form must be inspected.

When carrying out technological operations to localise dust, fine shavings, fumes, etc, it is necessary to use equipment of production plants with efficient general and local extraction ventilation ensuring the removal of harmful substances from the working zone.

CONCLUSIONS

1. Complex technology has been developed for assembling and welding structures of any geometrical form made of aluminium alloys containing lithium. This technology gives high-quality welded joints.
2. The standards determined for all parameters of the assembly components for welding result in the formation of high-quality welded joints.
3. The recommended methods of surface preparation for welding take into account the special features of the physico-chemical structure of the surface layers.

4. The use of TFA-15 fluxes makes it possible to reduce the amount of metal removed from the surface layers and the number of defects, and improve the formation of the penetration area, especially when welding without a backing strip.
5. To guarantee high quality of assembly for welding and stabilise the conditions of clamping the edges to the backing strip when welding joints of any geometrical form, it is recommended to use UPSF type equipment.

David St John and Arvind Prasad

University of Queensland, Brisbane, Australia

Abstract

Grain refinement is a critical technology for the successful production of cast parts; whether that be preforms such as extrusion billet or rolling slab, or near net-shape castings. A refined microstructure has many advantages with reduced defects and improved mechanical properties. This article describes the approaches to the prediction of grain size in Al-alloys refined by Al-Ti-B master alloys. Included are empirical approaches based on the generation and analysis of grain size data, the development of analytical equations, and the use of finite element approaches to the prediction of grain sizes. It is clear that researchers have a good ability to predict grain size of Al-alloys grain refined by Al-Ti-B master alloys, although there are still some outstanding challenges, particularly in considering more extreme solidification conditions and poisoning of the master alloys.

Keywords: Aluminum alloys; Analytical models; Casting; Constitutional supercooling; Finite element models; Grain refinement; Nucleation.

INTRODUCTION

Grain refinement is a critical technology for the successful production of cast parts; whether that be preforms such as extrusion billet or rolling slab, or near net shape castings. A refined microstructure has many advantages including a reduced propensity to solidification defects such as hot tearing, the formation of finer more dispersed porosity, improved processing through shorter diffusion distances for homogenization, and a finer recrystallized grain size. Therefore, the ability to predict the as-cast grain size for a range of alloys and master alloys cast by a range of casting methods and conditions is a valuable tool for the design of alloys and castings to deliver the desired mechanical properties.

Based on work from the middle of last century,^[1,2] a combination of Ti and B has become the most common addition to grain refine aluminum alloys, although there are some exceptions. Al-Ti-C master alloys are also effective grain refiners,^[3] and they have been proposed to be a solution in alloys where Al-Ti-B grain refiners are poisoned (grain coarsening), e.g., alloys containing Zr; however, there is some debate about whether Al-Ti-C master alloys may be poisoned as well.^[4] There are also new boride particles that are being proposed to overcome poisoning of grain size of Al-Si alloys.^[5] Sc additions are also

being investigated in high-performance alloys.^[6] However, by far the most common grain-refining master alloy is the Al-Ti-B range of master alloys.

Al-Ti-B master alloys are successful because they add TiB₂ particles that act as heterogeneous nucleation sites (weight-to-weight ratio of 2.2)^[7] and Ti solute (from dissolving Al₃Ti particles present in the master alloy) that acts as an extremely potent growth restricting agent,^[8] generating constitutional supercooling (CS).^[9] The most common master alloy is Al-5Ti-1B, which contains 2.2% Ti as TiB₂ and the other 2.8% provides an alloy melt with Ti solute. Al-3Ti-1B is also commonly used in recycled alloys where there is a high residual Ti content, while sub-stoichiometric grain refiners such as Al-3Ti-3B have been used in Al-Si alloys.^[10,11]

There have been many technical improvements to master alloys over the years, in particular the addition of fast-acting rod grain refiner into the launder during continuous casting, which minimizes settling of, and consequently improves the efficacy of, the TiB₂ particle addition in the casting. This is so effective that additions of less than 0.005 wt% Ti are made from a Al-5Ti-1B master alloy (on top of a typical residual Ti level of 0.005 wt% Ti in primary Al) to achieve a fine equiaxed grain size throughout the cast product.

There are various approaches that can be taken to the prediction of grain size. Comprehensive experiments can be undertaken, using good experimental design, to understand the key relationships, and then, empirical or semi-empirical equations can be used to describe the data. Alternatively, equations can be developed from an understanding of the physical phenomena^[12] and compared with select experiments. These models can be analytical or use Finite Element/Finite Difference approaches. Those developed on the basic physics can incorporate all the important physical phenomena, while those taking a more empirical approach need a sound understanding of the basic theory to guide their experimental design. There is considerable data and theoretical understanding that has been developed for the grain refinement of Al-alloys using Al-Ti-B master alloys; hence, both approaches will be described in this article.

PREDICTION: EXPERIMENTAL DATA AND EMPIRICAL PREDICTION

A large amount of experimental data has been generated investigating the factors that control grain refinement. Considerable research into the role of TiB_2 particles as heterogeneous nucleation sites, including crystallographic matching,^[7] formation of surface layers on the TiB_2 particles,^[13–15] and the role of particle size,^[16] has been able to guide the technology of master alloy production. Since the effectiveness of grain refiners may vary between producers,^[17] it remains difficult to definitively predict grain size rather than measuring it.

Another critical factor is the role of alloy chemistry on grain size, which has also been well studied.^[18–22] In particular, there has been some debate over the use of the supercooling parameter, $P = mC_0 \left(\frac{k-1}{k} \right)$, and the growth restriction factor, $Q = mC_0(k-1)$, where m is the liquidus gradient, C_0 is the amount of secondary alloying element and k is the partition coefficient, i.e., the ratio of the composition of the solid to that of the liquid in equilibrium. Physically, P is the total amount of supercooling available in a system, while Q is the rate of development of that supercooling as solidification begins.^[9] P may be useful in systems where there are few potential heterogeneous nuclei; in most grain-refined systems, it has been shown that Q is a much more effective predictor of the effectiveness of a solute addition in reducing the grain size. Importantly, different alloying additions have a wide range of relative Q -values (Table 1) with Ti additions being particularly potent in Al, hence the master alloy's effectiveness as a grain refiner. In multi-component alloy systems, the contribution from the individual elements can be summed to estimate the overall Q -value of an alloy.^[21] While there are some exceptions to this simplification,^[9,23] due to interaction between the elements,^[24,25] in most cases it at least provides a good estimate.

It is clear that both nucleation and alloy content are critical to understanding the development of grain size and consequently these are key factors in the prediction of grain size. The current authors (Easton and St John) generated a set of data across an extensive range of seven Al-based alloys, without and with different grain refiner additions.^[26] Furthermore, a range

Table 1 Partition coefficients, k_i , the liquidus gradients, m_i , and the relative value of the growth restriction factor (per unit concentration) for different elements in binary Al alloys. It is also identified whether the system is peritectic or eutectic

Element	k_i (wt%/wt%)	m_i (K/wt%)	$m_i(k_i^{-1})$ (K/wt%)	Maximum concentration (wt%)

of Ti solute additions were made to the alloys as well. It has been established that there is a very simple linear relationship between grain size (d), solute content (Q), and the potency and amount of active nucleant particle additions such that

$$d = a + \frac{b}{Q}, \quad (1)$$

where a is a constant related to the density of nucleant particles, and b is a constant related to the nucleant potency. For the master alloy used in that study, an empirical version of Eq. 1 was developed based on the data displayed in Fig. 1a where

$$d = \frac{32}{\sqrt[3]{pctTiB_2}} + \frac{652}{Q}. \quad (2)$$

However, this relationship breaks down in Al-Si alloys with Si contents greater than 2–3 wt% as Si additions above this amount lead to grain size coarsening (Fig. 1b), the reason for which is still not completely understood.^[27]

Other than the presence of nucleant particles and solute, the other factor that is critical for predicting grain size is the role of solidification conditions. This is somewhat complex with a number of different factors involved. Increasing the cooling rate, decreases the grain size, and it appears that there is a square root relationship between the cooling rate and the grain size^[21,28,29] (Fig. 1a) such that:

$$d = \frac{30.8}{\sqrt[3]{pctTiB_2}} + \frac{653.5}{Q\dot{T}^{1/2}}. \quad (3)$$

A change in solidification conditions may also change the source of the nuclei. For example, using a chill mold rather than a preheated graphite mold is known to reduce the grain size of a casting as the greater amount of thermal undercooling at, or near, the mold wall generates a large amount of additional nucleation events at lower superheats.^[30,31] For a 65°C superheat in the cast iron chill mold, the grain size is similar (cooling rate ~15°C/s) to that produced by the 15°C/s cooling rate in the pre-heated mold (Fig. 2). However, if the superheat is decreased to 35°C rather than changing the temperature gradient, as in the case of increasing the cooling rate, the intercept on the y-axis is decreased indicating an increase in the number of active nuclei (Fig. 2b). Hence, these two changes in solidification conditions lead to grain refinement but by different mechanisms that can be observed by considering the relationship between grain size, solute content, and nucleant particle additions through Eq. 1.

PREDICTION: MODEL-BASED APPROACHES

Semi-/Empirical-Approaches and Optimization of Grain Refiner Addition

Possibly, the simplest approach to prediction is the use of empirically derived equations to determine the grain size. As was shown in the last section this can be done in many casting situations. However, there is always a difference in solidification conditions between a commercial casting operation and data generated in the laboratory even if the cooling rates and solidification conditions are apparently similar. These variations can be difficult to verify in absolute terms but correlations can be made.

The generation of good grain size data sets for Al-alloys has enabled optimization of grain refiner additions

Fig. 2 Effect of solidification conditions on grain size with data obtained from four different Al-alloys with 0.005% TiB₂ addition as Al-3Ti-1B with Ti solute additions up to 0.05%. (a) Effect of cooling rate for alloys with $Q < 10$ K. Data was sourced from^[28] and (b) pouring into a cast iron chill mold with superheats of 35°C and 65°C

Source: Data was sourced from.^[77]

to achieve the same grain size at lower cost. Primarily these approaches involve the addition of lower cost Ti solute into the alloying furnace to reduce the amount of more expensive rod grain refiner being added to the launder.^[32]

One method involves addition of Ti solute to the minimum grain size in the Al-Si system (similar to 2–3 wt% Si, see Fig. 1b), rapid measurement of the grain size prior to casting, and from this a recalculation of the rod grain refiner addition based on the grain size is obtained.^[33] This is particularly effective in the production of secondary alloys where varying amounts of residual grain refiner are already present in the melt.

A modification of this approach is to use the empirical Eq. 2 to optimize the addition.^[34] If the grain refiner addition is already known, the grain size can be calculated. Then an algorithm using the relative costs of Ti additions into the alloy and rod grain refiner additions into the launder is able to generate the lowest cost addition rate. It was found that for a typical grain refiner addition level of 0.005 wt%, savings can be made for alloys with Q -values of less than approximately 10 K. For example, savings of approximately \$1/ton Al for alloys with a Q -value of 5 K can be achieved whilst maintaining the same grain size.

Analytical Approaches

The development of analytical approaches has received considerable attention over the last two decades. There are two main schools of thought that have emerged in predicting grain size—recalculence stifling (or extinction)^[35–39] and the role of CS in triggering new nucleation events.^[9,40–43] In principle, only the Interdependence Model by St John et al. (introduced shortly) is purely analytical. All other models

require some numerical recipe to solve the set of equations to predict grain size. However, for the purposes of this article, we define numerical techniques as those models that use Finite Element, Finite Difference, Cellular-Automaton approaches, etc.

Recalculence Extinction

The original approach was introduced by Maxwell and Hellawell^[35] who suggested that nucleation is triggered heterogeneously at some undercooling on inoculant particles. The potency of these inoculant particles was assumed to be the same. When a certain undercooling is reached, these particles trigger nucleation (following the classical nucleation theory) and the subsequent grain growth results in the release of latent heat. When the rate of heat released exceeds the imposed cooling rate recalculence occurs, the undercooling is reduced, and further nucleation stops.

Greer et al.^[36] followed the same idea but introduced two new ideas of inoculant particle distribution and nucleation on these inoculant particles via Free Growth. The Free Growth model suggests that larger particles require less undercooling to initiate nucleation and vice versa. For small solidifying systems, the Free Growth model predicted the grain size well.^[44,45] Greer et al.^[36] presented some grain size and grain density results, shown in Figs. 3 and 4. Figure 3 compares the results from the Maxwell-Hellawell and Greer et al. models. Notably, Greer et al.'s model shows grain size decreasing with Q (Fig. 2). In a similar vein, Men and Fan^[37] also analyzed the correlation between $1/Q$ and grain size on the basis that growth restriction increases the time and undercooling before recalculence sets-in. Using a spherical growth model of the nucleated grain, they proposed an empirical cube root relationship between grain size and $1/Q$ (Fig. 5).

Fig. 3 Plot showing the number of inoculants triggering nucleation based on Maxwell/Hellawell and Greer et al. models. Maxwell and Hellawell assumed nucleation on a set of particles with fixed characteristics and found two regimes: (a) in which there is 100% efficiency (one grain per particle), and (b) in which the number of grains saturates.

Fig. 5 Cube root correlation between grain size and $1/Q$ from Men-Fan model

Source: Adapted from Men-Fan.^[37]

More recently, Du and Li^[39] extended the solid–solid precipitation model of Kampmann-Wagner to liquid–solid transformations. They followed the Greer et al. Free Growth model for inoculant nucleation and also used a spherical growth model for the growth of nucleated particles. In fact, all models following the recalcification extinction idea assume (with good justification) spherical growth of grains. With this assumption, the simulation results are valid only for the initial stages of solidification when a spherical shape is thought to be stable. Their simulation results show that very early in solidification (less than 5 s before recalcification sets in) CS does not play a significant role and that nucleation is stopped by the on-set of recalcification. Figure 6 shows the results from their simulation.

Constitutional Supercooling

The importance of the contribution of CS to grain size was highlighted during the 1990s.^[8,19–21,46] From this, Qian et al.^[41] developed a rigorous prediction of grain size, d_{gs} . It was based on the form of Eq. 2 and the assumption that the first term in Eq. 4 is related to the growth of a grain producing sufficient supercooling ΔT_{cs} in front of the growing interface to trigger nucleation on nearby potent particles. The nucleation undercooling, ΔT_n (i.e., when equal to T_{cs}), at a distance x_{sd} from the interface was defined by the Free Growth model.^[36] Hence,

$$d_{gs} = D \cdot \Delta T_n / (v \cdot Q) + x_{sd}, \quad (4)$$

where D is the diffusion coefficient of solute in the liquid, and v is the velocity of the growing interface.

This model was further developed into the Interdependence Model^[42] with the realization that nucleation has a very low probability of occurring within the diffusion field in front of the growing grain and, therefore, the length of x_{sd} begins at the end of the diffusion field. The Interdependence

Fig. 6 Du-Li model results showing minimal effect of solute suppressed nucleation (SSN)

Source: Adapted from.^[39]

model is defined by Eq. 5, and it has three components of critical distance in order to predict grain size, as illustrated in Fig. 7. The first term in Eq. 5 is the growth distance x_{cs} of the previously nucleated grain sufficient to generate the necessary ΔT_{cs} to trigger nucleation on a particle of ΔT_n , the second term is the length x'_{dl} of the diffusion field to the point where ΔT_{cs} is achieved, and the third term is the distance x_{sd} to the location of the nearest particle of potency ΔT_n at least equal to ΔT_{cs} .

$$d_{gs} = \frac{Dz\Delta T_n}{vQ} + \frac{4.6D}{v} \left(\frac{C_l^* - C_0}{C_l^* (1-k)} \right) + x_{sd} \quad (5)$$

where C_0 is the alloy composition, C_l^* is the liquid composition at the interface of the growing grain, and k is the partition coefficient. This equation is able to predict the actual measured grain size data for a large number of Al alloys plotted in Fig. 1a, using literature values for ΔT_n , D , and v .^[42]

Nucleation will not occur during the growth of the previous grain until the diffusion field develops such that ΔT_{cs} equals ΔT_n at the end of the diffusion field. The combination of these two distances was referred to as the nucleation-free zone (NFZ).^[42] Simultaneously, Shu et al.^[43] realized that nucleation was unlikely to occur in the diffusion field, which they called the solute suppressed nucleation (SSN) zone. Note that the SSN zone does not include the distance of the grain growth to achieve ΔT_{cs} .

While recalescence stifling considers what stops further nucleation, the CS paradigm aims to estimate the

Fig. 7 Schematic representation showing the intersection between T_A and the $\Delta T_n - S_d$ curve indicating the location of the nucleation event, and the three regions that together establish the grain size of the microstructure: x_{cs} , x'_{dl} , and x_{sd} . The first two regions x_{cs} and x'_{dl} together represent a NFZ, where nucleation is not possible for the particle distribution described by $\Delta T_n - S_d$.^[42]

conditions that would trigger nucleation events. In either case, the length of the diffusion zone (or field) ahead of the growing interface is critical. A recent study compared three models (Du-Li, Shu et al., and Interdependence Model) and the μ MatIC numerical model.^[47] Shu et al. and Du-Li models are numerical models, and the diffusion field is described by analytical equations. This analysis showed that the four models produce a broad range of results. For example, if the input data is 0.2°C for ΔT_n and the values of v and D are $2 \mu\text{m/s}$ and $1.98 \times 10^{-9} \text{ m}^2/\text{s}$, respectively for the three analytical models, the respective values of x_{dl} are $24 \mu\text{m}$ for the Interdependence model, $61 \mu\text{m}$ for the μ MatIC model, $308 \mu\text{m}$ for the Du-Li model, and $1,947 \mu\text{m}$ for the Shu et al. model. If v is reduced to $1 \mu\text{m/s}$, the Interdependence and μ MatIC models produce close to the same result with $47 \mu\text{m}$ for x'_{dl} . The Interdependence and μ MatIC models predict x'_{dl} values of the same order of magnitude. The two other predictions are one order and two orders of magnitude greater, respectively. However, a significant issue in comparing models is that the input data available in the literature for v , D , and ΔT_n are all imprecise and can vary considerably. Unlike the Shu et al. and Du-Li models, the Interdependence model includes the term x_{sd} , which also contributes to the final grain size. Furthermore, Men-Fan and Du-Li models^[37,39] tend to support a minimal role of CS in triggering nucleation. This is in direct contrast to Interdependence and previous-related models (e.g., Winegard-Chalmers model^[40]). Therefore, one of the future challenges that emerges is to determine the relative importance of CS and recalescence in controlling nucleation, where CS is a dominant factor.

Regardless of such differences, similar to the Interdependence Model, the recalescence models also allow a good explanation of practical observations of unused inoculants in the melt. Moreover, additional similarities between Men-Fan and Interdependence models indicate that the grain size is a function of undercooling achieved, the average dendrite growth rate, and the consequent fraction solid formed (amount of grain growth). The reader is advised to exercise caution as different articles tend to use definitions of undercooling (or supercooling) slightly differently.

It has been rightly pointed out that analytical models are useful for understanding the mechanisms of grain refinement at play.^[37] As an analytical model, the Interdependence Model has become a useful way of analyzing the factors controlling grain size even when the values of D , v , and ΔT_n are not known. Despite the fact that the model was developed on the assumptions of near equilibrium solidification at the interface and the presence of potent particles, it has been found that the relationship between grain size and alloy chemistry ($1/Q$) defined by Eq. 1 holds for many casting environments. It has even been successful in highly dynamic environments such as high-pressure die casting^[48] and ultrasonically treated melts^[49] during solidification. The intercept of a $1/Q$ plot

indicates the limiting minimum grain size achievable while the slope can indicate the comparative potency of the active particles under constant casting conditions^[50] and the effect of casting conditions such as temperature gradient when the type and number density of particles are constant.^[28]

It is interesting to note that both the Interdependence model and models based on recalescence extinction have correlated well with experiments.^[36,44,45,51] On the other hand, the Interdependence Model predicts wave-like nucleation events. Such wave-like nucleation events have been recently verified in Al-Cu^[52] and Al-Si X-ray synchrotron experiments.^[53] These experiments also show significant buoyancy induced grain movements, as well as severe oscillations in dendrite-tip growth at early stages of dendrite growth, believed to be caused by thermo-solutal convection in the melt.^[53] Moreover, the sample size in the X-ray synchrotron in situ experiments is very small, and thermal gradients are usually present in such experiments. Predicting grain size within such a dynamic environment requires robust numerical models since analytical models are incapable of incorporating such complex interplay of events. Numerical models would be useful in such cases as discussed in the next section.

Numerical Modeling Approaches

Numerical techniques cover different areas of solidification—macroscopic heat flow calculations; heat and fluid flow for mold filling; grain growth models—either columnar or equiaxed, or simulating defect formation. For the specific case of predicting grain size, the numerical models have to include microstructure formation, specifically focused on equiaxed grains. With the focus on grain size prediction, simulating the number of nucleation events is critical. Different approaches may be taken for simulating the nucleation events:

1. Alloy liquidus: Nucleation events are assumed to occur at the alloy liquidus, which is an oversimplification that does not take into account differing nucleation conditions.
2. Continuous nucleation: Here the inoculant undercooling is taken into account. Nucleation is assumed to occur when melt undercooling is reached at or below the inoculant undercooling. In this case, all inoculants are assumed to nucleate at or below this undercooling.^[35] Nucleation is assumed to stop when recalescence pushes the melt temperature above the undercooling required for triggering nucleation. One particular potency of the inoculant particle is assumed in this model.
3. Inoculant distribution: Real casting practices inform us that inoculants have a distribution of sizes,^[44] and, therefore, would trigger nucleation at different undercooling values. This has been accounted for by

introducing the idea of using an undercooling distribution.^[54] In particular, a Gaussian distribution is often used.

There are several solidification models available that focus on equiaxed grain growth. Of note are the Rappaz-Thevoz^[55–57] and Beckermann^[58,59] models. They are both micro-macroscopic models (i.e., coupling microscopic grain growth with heat transfer from the solidifying domain) developed for simulating microstructure formation for a given solidification condition and have been the precursor to the later stochastic models based on Cellular Automaton (CA).^[60,61] A recent CAFD (Cellular Automaton Finite Difference) model is the μ MatIC model, developed by Lee et al.^[62–65] capable of simulating 1-D, 2-D or 3-D solidification conditions with or without thermal gradient and fluid flow (i.e., to simulate convection effects).

In this model, nucleation events within the domain can be triggered in two ways: by an assumed Gaussian distribution of the inoculants that results in random nucleation events within the domain, or by setting the inoculants at fixed positions. Grain size prediction work done using this model has used the latter nucleation scheme. At present, nucleation is deemed to occur at the alloy liquidus. Following nucleation at the liquidus, grain growth is allowed with the help of rules that constitute the CA model.

While there are several numerical models, the focus for this article is on solidification resulting in equiaxed growth of grains. Often times, the Gaussian inoculant distribution parameters have to be adjusted in simulations when validated by experimental results. The approach used by the μ MatIC model is that the nucleation sites are prefixed and nucleated grains are allowed to grow. The solute transport from these solidifying grains in terms of the diffusion length, x'_{dl} , is compared against that obtained by the Interdependence Model (as well as Du-Li and Shu et al. models presented above) and some conclusions are drawn.

Results from the μ MatIC model were briefly introduced in the previous section when comparing the length of the diffusion field from different models (the Shu et al. and Du-Li models, which are also numerical models, have already been referred to previously in this regard). This means that the results are compared long before physical impingement of grains occur. Furthermore, direct grain size prediction is not straightforward, as the final grain sizes observed in practice requires simultaneously taking into account several factors such as inoculant distribution within the melt, fluid convection, coarsening etc. Indeed, this represents a major challenge for numerical modeling of nucleation and grain formation to enable grain size prediction.

Summary of Advantages and Disadvantages

All predictions are based upon particular assumptions. Empirically based models make extrapolations based on

data from a particular system. The basic form of the data for grain refinement as shown in Fig. 1 and Eq. 1 has been found to be a very powerful tool for the prediction and analysis of grain refinement, in large part due to its simplicity. Analytically based physical models have been very powerful in providing a stronger theoretical basis for the empirical models and will be critical for understanding the difference between alternative manufacturing routes, for example, between conventional casting and Additive Manufacturing. The numerical models generate microstructure simulations and provide the researcher with the opportunity to stop an experimental simulation part way through, which is difficult to do experimentally. The main challenge is the computational power required particularly when moving to 3-D space predictions. The main issue in going beyond model systems that are relatively computationally simple is to incorporate all the factors involved particularly when the chemistry of a solidifying alloy is complex. Hence, all approaches provide complementary views of the grain refinement problem.

PREDICTION: CHALLENGES

It can be concluded that none of the analytical or numerical models is able to predict grain size in industrial castings without some fitting. They are essentially models for predicting nucleation, while the as-cast grain size is also determined by the degree of convection and gravity effects that cause the nucleated grains to move relative to each other during the early stages of solidification. However, the solute content through Q has been used^[17,33] to determine the relative grain size for an alloy, amount of added master alloy, and given casting conditions in order to optimize the cost of master alloy additions. Easton et al.^[26] used the form of $d=a+b/Q$ for fitting measured grain sizes for many alloys resulting in the empirical Eq. 2. For a given set of casting conditions, this is an approach that produces a reliable predictor of as-cast grain size for a range of alloy compositions for a particular alloy and amount of master alloy addition. As well as the issues in obtaining a fully predictive model, further challenges remain.

Poisoning—Si, Zr, Others

Predicting grain size in Al-Si alloys and other systems that demonstrate poisoning (i.e., grain coarsening), such as in Ti inoculated cast aluminum alloys when Zr is present, is a major challenge. The main issue is that the poisoning mechanism is not well understood. With respect to poisoning of Al-Si alloys, there is substantial data available^[21,66,67] and some theories,^[68–70] but they only explain poisoning in grain-refined alloys. Poisoning is also observed in unrefined alloys and therefore the validity of these theories is compromised.

The Interdependence Model provides a pathway to understand some of the factors that may contribute to poisoning.^[26,27] For instance, viscosity changes with alloy composition affect convection and solute diffusion, which can, in turn, affect grain nucleation and growth, and the impact of these changes on grain size can be assessed using the Interdependence Model. It would be worthwhile to consider this effect in future research.

Processing Parameters

One of the important factors in casting to consider is the presence of thermal gradients within the melt. The gradient is governed by the imposed cooling rate on the solidifying system, which in turn depends upon the mold material, size of the casting, etc. The effect of thermal gradient in predicting grain size has not been fully explored. The 'z' term in the Interdependence Model (Eq. 5) represents the fraction of CS required to initiate ongoing nucleation events. However, an exact description of 'z' and the relationship between 'z' and the thermal gradient has not yet been established. Further work on the impact of the thermal gradient on grain size has been initiated. It has been shown that the CS zone decreases and the amount of CS also reduces with an increase in the thermal gradient.^[71]

A pressing example where this is important is the prediction of grain size in additively manufactured components. One of the greatest challenges in additive manufacturing is obtaining parts with a fine equiaxed grain morphology,^[72] partly because the high thermal gradients promote epitaxial growth and also because grain refinement methods for steep temperature gradient environments have not yet been closely considered.^[73] Obtaining information about key variables including the thermal gradient, G , the growth rate, v , the diffusivity of alloying elements, D , and the distribution of nucleation particle undercooling, ΔT_n , will be critical to extend the prediction of grain size into this application.

CONCLUSION

Approaches for the prediction of grain size in aluminum alloys include empirical models based on comprehensive data sets, physically based analytical models, and numerical models. All approaches are important with their own benefits. The empirical approach has provided simple equations that have enabled grain size control in commercial operations. Coupling this with an analytical approach has allowed a fundamental understanding of the variations in the grain size data including identifying the mechanisms of grain refinement. The analytical models have also identified the factors that are important to consider in the development of a more rigorous approach to grain size prediction. Finally, numerical models have the potential to enable accurate prediction of grain size and morphology

with the benefit of visualizing solidification. These innovations have led to substantial improvements to grain refiner practice and promise further benefits into the future particularly in emerging manufacturing technologies such as additive manufacturing and the processing of metals under the influence of external fields.^[74]

Atom Probe Characterization of Nanoscale Precipitates in Aluminum Alloys

K. Hono

Abstract

Atomic Probe Field Ion Microscopy (APFIM) is used to solve many critical problems related to microstructures of metallic materials such as nanostructures that are composed of nanoscale precipitates dispersed in a matrix phase. The atom probe technique provides unique information on metallic nanostructures not attainable with other analytical microscopy techniques such as Transmission Electron Microscopy (TEM). In this article the an overview of the contribution of the atom probe technique to enhance the current understanding of solute clustering and characterization of fine precipitates of aluminum alloys.

Keywords: GP zones; Nanocomposite; Precipitation processes; TEM.

INTRODUCTION

The atom probe field ion microscope (APFIM) was originally developed as a tool for surface science by Muller and his coworkers in 1968;^[1] however, from the emerging stage of the technique, metallurgists realized that its use could solve many critical problems on the microstructures of metallic materials. By the 1980s, several groups started employing the atom probe technique for microstructural characterizations of metallic materials. It has also been applied to a wide variety of materials such as semiconductors and oxide superconductors. However, due to the poor electrical conductivity, the difficulty of specimen preparation, and the uniform microstructural features in these materials, the atom probe technique has not made much contribution to characterizations of nonmetallic materials. However, it has been successfully demonstrated that the atom probe is extremely useful for characterizing metallic nanostructures that are composed of nanoscale precipitates dispersed in a matrix phase. The atom probe technique gives unique information on metallic nanostructures that is unattainable with other analytical microscopy techniques such as transmission electron microscopy (TEM); it can detect light elements such as carbon, boron, oxygen, and nitrogen in a subnanoscale resolution. The atom probe has a very high spatial resolution in compositional analysis, and it can even measure the chemical composition of nanoscale particles embedded in a matrix phase. It can also detect small solute clusters that are not detectable by a high resolution electron microscope (HREM). Because of these unique features, the atom probe technique has been widely used for nanoscale analysis of metallic microstructures. In particular, it has been demonstrated that this technique is useful in characterizing the microstructural evolution in

the early precipitation stage of age-hardenable aluminum alloys, in which clustering of solute atoms plays a critical role in the microstructural evolution. This paper intends to give an overview in the application of the atom probe technique in characterizing the microstructures of various aluminum alloys of commercial importance.

Most wrought aluminum alloys are strengthened by age hardening. The strength achieved by age hardening originates from the interaction between dislocations and precipitate particles, and controlling the dispersion of fine precipitates is necessary to optimize the strength by age hardening. Precipitation in commercial aluminum alloys usually starts from the formation of metastable coherent precipitates (or solute clusters) called Guinier-Preston (GP) zones, and these evolve to more stable phases as they are aged for longer times. Such microstructural evolution occurs because GP zones have less interfacial energy than the equilibrium phases with a different crystal structure; thus the nucleation barrier of the GP zone formation is significantly smaller than those of the equilibrium phases. Typical size of GP zones is in the order of tens of nanometers; thus the chemical characterization of these precipitates cannot be easily carried out by an analytical transmission electron microscope (AEM), because these particles are embedded in a matrix. It is also well-known that the kinetics and even the precipitation products are influenced by the trace addition of solute elements. For example, it has been known that a trace addition of Sn (~0.01 at.%) significantly reduces the precipitation kinetics of the GP zones at low temperature aging (<130°C), while it enhances the precipitation reaction at high temperature aging (>160°C). This is because the Sn atoms are bound to vacancies to suppress the formation of GP zones, while Sn precipitates effectively act as the heterogeneous nucleation sites for θ'

phase at high temperature. In order to understand the role of these trace elements, it is necessary to observe the clustering behavior of trace solute elements in aluminum alloy. The direct observation of these solute clusters would be possible only with the atom probe technique.

The purpose of this paper is to give an overview on the contribution of the atom probe technique on our current understandings of solute clustering and characterization of fine precipitates in aluminum alloys. For further reading, it is noted that two review articles on the application of the atom probe technique to the studies of aluminum microstructures are already available,^[2,3] the latter containing a complete list of literature.

OVERVIEW OF THE ATOM PROBE TECHNIQUE

The atom probe field ion microscope (APFIM) is a combination of a field ion microscope (FIM) and a time-of-flight mass spectrometer. Using an atom probe, it is possible to detect individual atoms that are ionized from a sharp needle-like metallic specimen. Atoms are ionized by the field evaporation process under a very high electric field applied on a sharp metal tip. This ionization occurs from the surface of the specimen regularly, so it is possible to achieve atomic layer resolution in the compositional analysis. Two types of atom probes are currently used: one is a conventional time-of-flight atom probe, the schematic illustration of which is shown in Fig. 1a. By selecting a small region using an aperture called the *probe hole*, atoms are collected only from the region selected by the probe hole. The physical dimension of the probe hole is typically

2 to 3 nm in diameter, but its projected size is less than 5 nm. Atoms are evaporated from the surface continuously; thus atoms are collected in the three-dimensional volume covered by the probe hole. However, in this atom probe, the information on the lateral positions of the atoms is not recorded. Hence, the data chain of the collected atoms can be converted to a one-dimensional depth profile by scaling the depth in proportion to the number of collected atoms. Because of the nature of the information obtained from this type of atom probe, the conventional time-of-flight atom probe is now called the one-dimensional atom probe (1DAP) to differentiate it from the recently developed three-dimensional atom probe (3DAP).

The 3DAP obtains the information on the lateral position of atoms using a position sensitive detector (PSD) as shown in Fig. 1b while measuring the time-of-flights of individual atoms. From the time-of-flight, the mass of each atom is determined. At the same time, from the (x, y) coordinate determined by the PSD, position of the atom is recorded. This gives a two-dimensional elemental map with a near-atomic resolution. The lateral spatial resolution is limited by the evaporation aberration that occurs during the ionization of atoms on the surface. However, the error originating from the evaporation aberration does not exceed 0.2 nm, and this is still the lowest of the errors achieved by any existing analytical instruments. Atoms are collected sequentially from the tip surface; hence, the number of atoms is proportional to the depth from the original surface of the specimen. Thus, z coordinate can be assigned to each atom in proportion to the order of detection. By this way, a three-dimensional elemental map can be drawn as schematically shown in Fig. 1b. Since field evaporation occurs layer-by-layer in low index planes, the

Fig. 1 Schematic illustrations for the principle of (a) a conventional time-of-flight atom probe and (b) a three-dimensional atom probe (3DAP)

reconstructed 3D elemental map shows the layers corresponding to the atomic planes in the depth direction. This type of atom probe was originally developed as a position sensitive atom probe (PoSAP) by Cerezo et al. in 1988,^[4] followed by Blavette et al. in 1993^[5] as a tomographic atom probe (TAP). Since the AP data detected by a PSD give three-dimensional elemental maps, this type of AP is now generally called a three-dimensional atom probe (3DAP).

Although earlier 3DAP instruments could not achieve a high mass resolution in the time-of-flight mass analysis, the modern 3DAP instruments are equipped with a reflectron energy compensator, and is able to achieve a mass resolution, $m/\Delta m$, larger than 300.^[6] With this performance, most of the alloying elements contained in complicated commercial aluminum alloys can be identified without any ambiguity. For further details of the atom probe technique and atom probe tomography, refer to recent textbooks by Miller et al.^[7,8]

In order to demonstrate the unique analytical capability of the 3DAP technique, typical data obtained from a nickel base superalloy (Inconel X-760: Ni-16.8Cr-6.5Fe-2.9Ti-1.5Al) is shown in Fig. 2. Nickel-base superalloys form nanoscale cuboidal precipitates with the $L1_2$ structure, $Ni_3(Al, Ti)$, and the Al and Ti enriched regions in the elemental map correspond to these precipitate particles. Figure 2a shows a three-dimensional elemental map of Al and Ti atoms in this alloy. From the number density of these solute atoms, the morphology of $Ni_3(Al, Ti)$ particles can be clearly seen. The chemical compositions of these nanometer sized particles can be determined by counting the number of solute atoms as a function of total number of detected atoms within the volume of the analysis as shown in Fig. 2b. By selecting the volume for analysis

smaller than the particle size, the chemical compositions of the nanosized particles can be accurately calculated without any influence from the matrix phase. In the $L1_2Ni_3(Al, Ti)$ precipitates, Al and Ti occupy Al sublattice of the Ni_3Al ordered phase. Corresponding to this structure, the atomic layers can be resolved in the [001] direction within the particles as shown in Fig. 2c. This demonstrates that the 3DAP has an atomic resolution in the depth direction of the analysis. Figure 2c is an enlarged elemental map of one of the γ/γ' interfaces in Fig. 2a, in which the elemental distribution near the interface is atomically resolved. As demonstrated in this data, the 3DAP gives very accurate compositional information on the interface of nanosized particles embedded in a matrix phase. This type of analysis is not possible with an analytical transmission electron microscope (AEM) because of the morphology of a TEM specimen. Figure 3 shows schematic illustration of a TEM thin foil specimen in which nanoscale particles are dispersed. Using a modern TEM equipped with a field emission gun, it is possible to converge an electron beam to less than 1 nm in diameter. However, since the foil thickness is normally larger than 20 nm, the electron beam spreads by scattering in proportion to $t^{3/2}$, where t is foil thickness. Assuming that the foil thickness is 20 nm, nanometer sized particles will be completely surrounded by the matrix. In such a case, energy dispersive x-ray spectroscopy (EDS) or electron energy loss spectroscopy (EELS) signals containing the chemical information of the nanoparticles will always contain the information from the matrix phase as shown in Fig. 3. Since GP zones and other metastable precipitates commonly observed before overaged conditions are something like Fig. 3, there is a

Fig. 2 Typical 3DAP data obtained from an Inconel X-760 alloy (Ni-16.8Cr-6.5Fe-2.9Ti-1.5Al): solution heat treated and aged for 75 hr at 750°C. definite merit in characterizing the microstructures using atom probe than using analytical electron microscopy.

In the following section, atom probe characterization results of various aluminum alloys of commercial interests are reviewed.

ATOM PROBE STUDIES OF PRECIPITATION PROCESSES

Al-Cu Alloy

Al-Cu alloy is the most fundamental system for the precipitation hardening aluminum alloys. The precipitation sequence of this system is generally described as:^[9]

Among these, all metastable precipitates except for θ are platelet lying on $\{001\}$ planes. GP zones are fully coherent plates of Cu atoms whose thickness is generally thought to be a monoatomic layer. This model is known as Gerold's model for GP zones in Al-Cu alloys:^[10] however, there are several other models to describe how Cu atoms aggregate in the GP zones.^[11–14] Controversies on the structure of the GP zones in Al-Cu alloys up to 1988 are summarized in a review paper by Gerold.^[15] It should be noted that the GP zones are fully coherent aggregates of solute atoms and they do not have their own unique structure. The structure is the same as the matrix, thus the model describes only the morphology and concentration of solute atoms in the zone and the resultant strain field near the solute aggregates. These structural models were proposed so that they give relatively good agreement with the experimentally observed diffuse scattering intensity; thus the structural model derived from these experiments may not be unique. Gerold's model describes the GP zone as a monolayer $\{002\}$ plane containing 100% Cu atoms in it, while others think the GP zones are more diffuse, e.g., Matsubara and Cohen^[14] proposed that some of the GP zones are composed of more than one atomic layer of nearly pure Cu $\{002\}$ planes. They also proposed that the transition from the GP zones to the θ'' is continuous rather than discrete.

Many HREM observation results on the structure of the GP zones have been published, but it was shown that the image contrast changes depended on the imaging conditions as well as the thickness of the foils. However, recent HREM work by Karlik and Jouffrey^[16] with careful image simulation suggests that there are indeed multilayer GP zones. Direct observation of the GP zones in Al-Cu alloy by FIM was successful to observe monoatomic layer array of Cu atoms on $\{002\}$ planes;^[17] but evidence for multilayer GP zones has also been published.^[18] Figure 4 shows FIM images of (a) a GP zone and (b) θ'' precipitate

Fig. 4 He field ion images of a GP zone and θ'' precipitates observed in Al-Cu based alloy
Source: Reproduced with permission from Hono et al.^[38]

observed in an Al-Cu based alloy. Individual Cu atoms are observed in a single atomic row, being consistent with the model of monoatomic layer GP zone. θ'' precipitate shows two brightly imaging rows separated by some aluminum matrix layers, being consistent with the classical model for θ'' which are two Cu {002} atomic layers separated by three Al {002} layers. The origin of these bright contrast from Cu rich layers is the preferential retentions of Cu atoms on the surface of the FIM tip. Since Cu atoms have higher evaporation fields than Al atoms, Cu retains on the surface even when Al atoms are evaporated on the surface. This causes a larger local electric field, resulting in bright atomic contrast.

The chemical analysis of such a fine object is very challenging. In order to measure the chemical composition of the GP zones in Al-Cu alloys, monoatomic layer resolution is required. Direct atom probe analysis results showed that evaporation behavior changes near the GP zones because Cu has a higher evaporation field than Al.^[19,20] Thus, although the depth profiling of atomic resolution is possible from the matrix, when GP zones appear on the surface, Cu is strongly retained on the surface and the layer-by-layer evaporation behavior is deteriorated near the GP zones. Thus, it was not successful to obtain accurate atomic layer resolution, but the result showed that both the concentration profiles of the GP zone and θ'' precipitates might be somewhat diffuser. Also, it was suggested that the maximum concentration of Cu may not reach 100% Cu as determined by other methods.^[14]

Recently, Bigot et al.^[21] investigated the GP zones in Al-1.7 at.%Cu alloy using 3DAP, and succeeded in reconstructing thin Cu rich plates on {002} planes as shown in Fig. 5a. This data was obtained by analyzing the specimen in the [001] direction and the GP zones on (200)_{Al} and (020)_{Al} are successfully imaged. The concentration depth profile calculated from this data shows the maximum concentration of Cu is 35 at.%, as shown in Fig. 5b. However,

Bigot et al. attributed this to the evaporation aberration. Assuming that the GP zone is a single layer, they estimated the maximum Cu concentration to be 50 at.% or higher. In principle, atom probe data give the highest spatial resolution in the depth direction of the analysis, because low index planes evaporate layer-by-layer. However, they did not succeed in reconstructing Cu layers from the GP zones analyzed in the vertical direction. The Cu concentration estimated from the analysis in the perpendicular to the plate was only 35 to 20 at.%, similar to the earlier work by 1DAP.^[20] They attributed this to the preferential retention of Cu atoms during the field evaporation process of the atoms with much higher evaporation fields than the Al matrix.

While FIM observation made a certain contribution in understanding the morphology of the GP zones, neither 1DAP nor 3DAP gave the definite answer to the structure and chemical composition of the GP zones in Al-Cu alloys. If more rigorous control of field evaporation can be made by cooling down specimens below 10 K under an ultrahigh vacuum condition, the difference in evaporation field of Al and Cu may become closer. In such a case, real atomic analysis of the monoatomic layer plate embedded in a matrix may become possible. It is noteworthy to mention that recent high angle annular dark field (HAADF) imaging investigation using a scanning transmission electron microscope (STEM) observed multilayer GP zones as well as single layer GP zones.^[22] Thus, the concentration change of the GP zone may be somewhat diffuser than it was thought previously.

Al-Cu Alloy with Trace Addition of Sn

The influence of the precipitation kinetics of Al-Cu alloys by trace additions of Cd, In, and Sn, all of which have strong binding energy with vacancies, is a classical subject of precipitation studies in aluminum alloys.^[23] Addition

Fig. 5 (a) 3DAP Cu map obtained from GP zones in Al-1.7 at.%Cu alloy. The GP zones are imaged as plates on {002} Al planes. The analysis direction was [002]. (b) Concentration depth profile of the GP zone indicated by an arrow in (a)

of these elements suppresses the kinetics of the GP zone formation, while it enhances the θ' precipitation. The suppression of the GP zone formation during low temperature aging has been attributed to strong Sn-vacancy interaction, by which diffusion of Cu is suppressed because the vacancies that are necessary for diffusion of Cu is captured by Sn.^[24] As to the enhanced kinetics of the θ' precipitation during high temperature aging, several mechanisms have been proposed,^[25–27] but TEM observation results showing θ' plate nucleating heterogeneously on Sn particles strongly suggests that the heterogeneous nucleation of θ' platelets on the Sn particles is the most probable mechanism to explain the high temperature aging kinetics.^[28] Using IDAP and TEM, Ringer et al.^[29] confirmed this result; in addition, they found evidence for Sn cluster formation in the early stage of aging. Since vacancies are captured by Sn atoms, they tend to form clusters in the early stage, leading to homogeneous distribution of Sn particles, although the driving force for the precipitation is low because of the low supersaturation. Figure 6 shows a 3DAP map of Al–1.7Cu–0.01Sn (at.%) alloy aged for 3 min at 160°C.^[30] Red and blue spheres correspond to Cu and Sn atoms respectively, and black dots correspond to Al atoms. The (002) atomic layers are observed, demonstrating that this 3DAP data have an atomic layer resolution in the depth direction of the analysis. Two rows of Cu atoms are observed, which is θ'' precipitate, having two (002) Cu layers separated by three Al (002) layers. The aggregate of Sn atoms corresponds to a Sn particle. The Sn particle and the θ'' plate are in direct contact with each other, suggesting that Sn particles act as heterogeneous nucleation sites for the θ'' . θ'' precipitates can precipitate without Sn particles, but this 3DAP analysis result indicates that Sn can act as heterogeneous nucleation sites for θ'' .

Fig. 6 3DAP elemental map of Cu and Sn in the early stage of aging of Al–1.7Cu–0.01Sn alloy aged for 3 min at 160°C

Al–Cu Alloy with Trace Addition of Mg and Ag

Trace additions of Mg and Ag in Al–Cu alloy leads to fine and uniform dispersion of plate like Ω phase on the $\{111\}$ Al planes in addition to the θ'' precipitates on the $\{001\}$ Al planes.^[31,32] A typical micro structure of an aged Al–1.7Cu–0.3Mg–0.2Ag alloy is shown in Fig. 7. In this micrograph, uniformly dispersed platelets along the (211) traces are Ω , and the platelets with the [011] trace are θ'' . The Ω phase shows high thermal stability and resistance to coarsening compared with the θ' phase; thus, Al–Cu based alloy with trace additions of Ag and Mg exhibits improved high temperature strength.^[33] The structure of the Ω phase was studied by Knowles and Stobbs^[34] and Muddle and Polmear,^[35] and more recently by Garg and Howe,^[36] all of whom suggested that the Ω phase has a very similar structure to the equilibrium phase in Al–Cu binary alloy, θ . Using an analytical electron microscope (AEM), Muddle and Polmear^[35] showed that Ag is segregated at the Ω /matrix interfaces. Atom probe field ion microscopy (APFIM) studies by Sano et al.^[37,38] showed that the Ω phase has the same Cu concentration as the θ (Al₂Cu) phase with the only difference in segregation of Ag and Mg at the Ω /matrix interfaces, and this suggests that both Ω and θ are chemically equivalent. The segregation of Ag and Mg at the interface was further supported by an AEM study by Howe^[39] using a field emission TEM. Thus, there is now good agreement in the literature regarding the structure and the chemical nature of the Ω phase.

The mechanism by which Ω precipitates uniformly having a habit plane on $\{111\}$ has been a subject of many investigations. Taylor et al.^[32] suggested that precipitation of Ω may occur from a precursor phase, Mg₃Ag, on the $\{111\}$ planes, but Cousland and Tate^[40] did not find such a

Fig. 7 TEM bright field image of Al–1.7Cu–0.3Mg–0.2Ag alloy aged at 190°C for 8 hr. z [011]. Thin plates with (211) trace are the Ω phase on $\{111\}$, those with [011] trace are θ' precipitates on (001)

phase at any stages of aging. Kerry and Scott^[41] proposed that the solid solution with Ag and Mg reduces the stacking fault energy, increasing the density of the {111} stacking fault at which Ω is heterogeneously nucleated. Abis et al.^[42] proposed that there is a Ω' phase as a precursor of Ω , and these act as heterogeneous nucleation sites for Ω , but the presence of such a precursor phase was not confirmed by a recent electron microscopy study by Ringer et al.^[43] Using a conventional atom probe, Hono et al.^[44] reported that Ag and Mg clusters form in the as-quenched stage and these evolve into co-clusters after a very short time aging (15 sec at 180°C). Small precipitates containing Cu, Ag, and Mg detected by APFIM after 30 sec aging at 180°C were identified as a very fine Ω phase and it was speculated that this nucleation takes place at the sites of the Mg–Ag co-clusters. However, the role of the Mg–Ag co-clusters in the nucleation stage of the Ω phase was not clearly understood with this work, because the conventional AP did not reveal any information on the morphology of the clusters and their link with the subsequent precipitates.

In order to observe the microstructural evolution process from clusters to precipitates in an Al–Cu–Mg–Ag alloy more precisely, Reich et al.^[45] revisited this alloy system using a 3DAP. Figure 8a shows a 3DAP elemental map of solution treated Al–1.9Cu–0.3Mg–0.2Ag (at.%) alloy. All solute atoms, Cu, Mg, and Ag atoms, are homogeneously dissolved in the matrix forming a supersaturated solid solution. The layer pattern observed in the Al map is originated

from the (111) planes, thus this 3DAP elemental map has an atomic layer resolution. Figure 8b shows an elemental map obtained from the same alloy aged for 15 sec at 180°C. An aggregate of Ag and Mg atoms is observed in the elemental map. The number of Ag and Mg atoms involved in the co-cluster ranges from 40 to 80 considering the fact that the detection efficiency of the microchannel plate (MCP) detector is less than 60%. The ratio of Mg to Ag atoms in these clusters is close to 1:1. The shape of the clusters is not well-defined in this stage, and Cu atoms are not incorporated in this cluster. Unlike the previous conventional AP results,^[43,44] this 3DAP data clarifies the morphology of the co-clusters in the earliest stage of formation. Such clusters do not give any contrast in TEM images, and only the APFIM can give direct evidence for the presence of Ag–Mg co-clusters.

Following the clustering stage, plate-like precipitates appear on the {111} planes as aging continues. Figure 9 shows a 3DAP elemental map obtained near the (111) pole of the specimen aged for 10 hr.^[46] The (111) atomic planes are resolved in this analysis. The plate like precipitate lying on the (111) planes is an Ω precipitate, and the other platelet inclined by 54.5° from the Ω is a θ' precipitate on the (100) plane. As seen from this example, 3DAP data reconstruct the morphology of the two plate-like precipitates on different habit planes quite accurately. The concentration depth profiles measured in the normal direction to the platelets are shown in Fig. 9b,c. The concentration profiles

Source: Reproduced with permission from Hono.^[46]

across the Ω , shows that Ag and Mg atoms are no longer incorporated within the precipitate, but they are strongly segregated to the broad $\Omega/a\{111\}$ interface. The segregation appears to be restricted to one or two atomic layers, and no Mg atoms are detected within the precipitate. The concentration of the Ω , is close to 33at.%Cu, which is consistent with the θ phase (Al_2Cu). This suggests that Ω , is chemically equivalent to θ . The chemical composition of the θ' precipitate observed in Fig. 9c is also close to

33at.%Cu, but this precipitate does not contain any Ag and Mg atoms.

It was also demonstrated that 3DAP can map elemental distributions near a growth ledge of a plate-like precipitate. A ledge is clearly observed as the change of thickness of the Ω , plate as shown in Fig. 10.^[45] Although Ag and Mg atoms are strongly segregated to the broad interface of the Ω , no segregation of Ag and Mg atoms occurs at the ledge riser, because this interface has a large misfit

with the matrix and the coherency is lost. The height of the ledge corresponds to twelve $(111)_{\text{Al}}$ atomic layers, corresponding to the three unit cell thickness of the Ω . Such a large ledge probably corresponds to the misfit compensating ledge as proposed by Fonda et al.,^[47] by which the strain in the vertical direction is relieved by placing one misfit dislocation. Since Ag and Mg atoms are segregated only on the broad interface of Ω/α , redistribution of Ag and Mg atoms must occur during the ledge migration. Thus, ledge migration, in other words, thickening of the Ω plate, should be controlled by the diffusion of Ag and Mg atoms as well as Cu atoms. Recently, using a high angle annular dark field (HAADF) imaging technique, Hutchinson et al.^[48] obtained a Z-contrast image confirming segregation of Ag atoms on two atomic planes of the broad interface, but the mechanism why Ag atoms segregate to two atomic layers is not well explained.

The 3DAP data obtained from the Al–Cu–Mg–Ag alloy most clearly demonstrate the excellent feature of the 3DAP technique that is suitable for characterizing solute atom clustering, segregation, and precipitation that occur during the microstructural evolution of age-hardening aluminum alloys.

Al–Cu–Li Alloy with Trace Addition of Mg and Ag

Trace additions of Ag and Mg to Al–Cu–Li alloy cause a uniform dispersion of the T_1 phase,^[49,50] while T_1 precipitates heterogeneously at grain boundaries in Al–Cu–Li ternary alloys. Although the precipitate product is different from

the Ω in Al–Cu–Mg–Ag alloys, it is in common with the Al–Cu–Mg–Ag alloy that the uniform dispersion of thin plate-like precipitates on the $\{111\}$ planes is triggered by the addition of Ag and Mg. Ω and T_1 phases are structurally and morphologically similar,^[51] so it was anticipated that a similar mechanism is responsible for the uniform dispersion of the T_1 phase in the Al–Li–Cu–Mg–Ag (Weldalite) alloy. The aspect ratio of T_1 is much larger than that of Ω and they are very thin plates. Figure 11 shows 3DAP analysis results of a T_1 plate observed in an Al–5.0Li–2.25Cu–0.4Mg–0.1Ag–0.04Zr alloy aged for 10 hr at 180°C together with a HREM image of a T_1 plate.^[52] Cu and Li are the major elements detected from the T_1 plate. The chemical composition determined from the 3DAP result slightly deviates from the one expected from the stoichiometry of Al_2CuLi , probably because of the unstable ionization behavior of the atoms near the T_1 precipitate that contains Li with a very low evaporation field. As in the case of the Ω phase in the Al–1.9Cu–0.3Mg–0.2Ag alloy, Ag and Mg atoms appear to be present at the T_1/α interfaces. Since the thickness of the precipitate is only one unit cell thick of the T_1 (four $\{111\}$ matrix planes), the segregation of Ag and Mg atoms is not visually clear from the elemental map. However, the concentration depth profile obtained in the normal direction to the T_1 plate suggests that the Ag and Mg atoms are segregated at the T_1/α interface rather than being partitioned in the precipitate.

Although segregation of Ag and Mg atoms at the T_1/α interface is similar to Ag and Mg segregation at the Ω/α interface, it was found that the clustering behaviors of Mg and Ag atoms are quite different in Al–Cu–Li–Mg–Ag and

Fig. 11 (a, b) 3DAP elemental maps of a T_1 precipitate observed in an Al–5.0Li–2.25Cu–0.4Mg–0.1Ag–0.04Zr alloy aged for 10 hr at 180°C and (c) concentration depth profiles calculated from the 3DAP data (Reproduced with permission from Murayama and Hono)^[52]

Al–Cu–Mg–Ag alloys. Unlike the Al–Cu–Mg–Ag alloys, no evidence for Ag–Mg co-clusters has been obtained.^[52] After several minutes' aging, only clustering of Mg atoms was observed. Thus, the mechanism of the nucleation of the T_1 appears to be different from that of Ω . The fact that Mg and Ag atoms do not form co-clusters suggests that Li additions affect the interactions between Mg and Ag atoms significantly. This observation is interesting when it is compared to the case of Al–Cu–Mg–Ag alloy, in which co-clusters of Mg–Ag atoms are formed after only several seconds' aging at 180°C.^[44,45] The absence of such Ag–Mg co-clusters in Al–Cu–Li–Mg–Ag alloys indicates that the interaction between Mg and Ag atoms is strongly influenced by the presence of Li.

Al–Cu–Mg Alloys

The precipitation process of Al–Mg–Cu alloys within the $\alpha + S$ (Al_2CuMg) two phase region has been a subject of numerous studies, because this is the base system for the 2000 series of aluminum alloys. The precipitation sequence of this alloy was described as:

by Silcock,^[53] but according to more recent work by Gupta et al.,^[54] Radmilovic et al.,^[55] and Ringer et al.,^[56] the structural difference between S' and S are trivial; thus S' is simply denoted as S . The age hardening curve of this alloy has two distinct stages: the first stage is a rapid hardness increase which occurs within 1 min aging at temperatures ranging from 100 to 240°C.^[57,58] The hardness increase during this period accounts for approximately 60% of the total hardness increase observed at the peak hardness condition, and it was recently proposed that this quick age hardening response may be used for bake hardening of body sheet aluminum alloy.^[59] After this rapid hardening, the hardness curve has a long plateau (~100 hr at 150°C), then the specimen starts to harden again and reach the peak hardness (the second stage). The origin of this characteristic age-hardening behavior was widely studied in the past, and it has been generally accepted that the first stage is associated with the formation of GPB zones, and the second stage is attributed to the precipitation of the S phase following Silcock.^[53] Recently, using APFIM, Ringer et al.^[60] proposed that the initial rapid hardness increase is caused by clustering of a few Cu and Mg atoms, and the second stage hardening is due to the GPB zones which start to form near the end of the hardness plateau. However, it is difficult to tell the solute clusters of few atoms from the atom probe concentration profile of the alloy containing a few atomic percent solute level, because even statistical fluctuation may look like clusters. More recently, Zahra et al.^[61] claimed that the initial rapid hardening is due to the precipitation of GPB

zones based on their thermal analysis results; however, no microstructural evidence for the presence of GPB zones in this stage was reported. On the other hand, Ratchev et al.^[59] attributed the rapid hardening to the formation of S'' phase (or S) on dislocations, by which dislocations are locked. Although the precipitation process of Al–Cu–Mg based alloy has been studied for a long time, there have been such controversies regarding the origin of the initial hardening response, and this is mainly because it has not been possible to observe solute distribution in the earliest stage of aging where hardness drastically changes.

Using 3DAP, Reich et al.^[62] observed the change in the distribution of solute atoms in Al–1.1Cu–1.7Mg alloy as a function of time at 150 and 200°C. Figure 12 shows 3DAP elemental maps of Al, Mg, and Cu atoms during aging at 200°C. The corresponding hardening stages are also indicated in the hardness-time curve. After 1 min aging, no evidence for Cu–Mg cluster formation is found. However, after aging for 60 min, which is the end of the plateau and beginning of the second stage hardening, 3DAP maps show some tendency of Cu–Mg co-clustering. Statistical analysis of this data suggested that there is a positive correlation between Cu and Mg atoms. At the peak hardness condition, needle-like precipitates in which Cu and Mg are enriched are observed clearly. These needle-like precipitates are attributed to the GPB zones which uniformly precipitate in the matrix. This series of elemental maps suggests that the initial rapid hardening that occurs within 1 min aging is not attributed to the GPB zone formation nor to the formation of Cu–Mg co-clusters. TEM observation indicated that only the heterogeneous precipitation of S phase along dislocations occurs during this short period of aging at 200°C, but no evidence for heterogeneous precipitation of S was found even after rapid hardening at 150°C. Thus, they concluded that the initial hardening is most likely to originate from solute-dislocation interaction as a result of enrichment of Mg and Cu atoms to the dislocations. This proposal was recently supported by coincidence Doppler broadening of a positron annihilation radiation study by Nagai et al.,^[63] which strongly suggests that the vacancies trapped by Mg atoms migrate to vacancy sinks, where vacancy–Mg–Cu complexes are formed after 1 min aging. Although atom probes can observe distributions of solute atoms, it is not possible to obtain the information on vacancies. On the other hand, positron annihilation studies can provide the information on the interaction between solute atoms and vacancies. Vacancies play a critical role in the kinetics of age hardening of aluminum alloys; thus the complementary use of atom probe and positron annihilation methods will shed light on many remaining problems in the precipitation processes of aluminum based alloys.

Al–Mg–Si Alloys

6000 series Al–Mg–Si alloys are one of the most widely used medium strength age-hardenable aluminum alloys,

Fig. 12 3DAP elemental maps obtained from Al-1.1Cu-1.7Mg alloy aged at 473 K for (a) 1 min, (b) 60 min, and (c) 480 min. The corresponding aging stages are indicated by arrows in the hardness curve (Reproduced with permission from Reich et al.)^[62]

and their precipitation processes and the kinetics of the age-hardening effect have been a subject of numerous studies since the 1960s.^[64–67] Due to the recent demand for the weight reduction of automobile bodies, the research interest in the kinetics of age hardening of Al–Mg–Si alloys has been revived,^[68] because Al–Mg–Si alloys have a good combination of strength and formability. The widely accepted precipitation sequence of this system is:^[69]

Supersaturated $\alpha \rightarrow$ solute cluster $\rightarrow$ GP zones (spherical)

The aluminum alloy sheet for automobile body applications have to have a good formability in the T4 condition (solution treated, quenched, and naturally aged) and must be age-hardened during the paint bake process of 30 min at 175°C (bake hardening). However, the bake hardening after natural aging becomes lower than that right after a solution heat treatment. In 1967, Pashley et al.^[66] studied the kinetics of the two-step aging process, and they proposed that the clusters that form during natural aging affect the age-hardening kinetics in the subsequent artificial aging. Using 1DAP, the presence of co-clusters of Mg and Cu atoms was examined by Edwards et al.^[70,71] and Murayama

et al.^[72] More recent 3DAP studies of Al–Mg–Si alloys^[73] revealed that the solute ratio in clusters, GP zones, and β'' precipitates vary depending on the alloy compositions. They found that there was a correlation between the atomic ratio of Mg:Si in these metastable precipitates and the alloy composition. Although the atomic ratio in the clusters and the GP zones does not change during aging, the content of Si and Mg atoms appeared to increase as they grow. Based on these observations, they concluded that there is no discrete distinction between the clusters and the GP zones; the latter can be imaged with TEM as they are more concentrated with solute atoms. They also found that the atomic ratios in the β'' precipitates are also the same as those in the GP zones.

In commercial Al–Mg–Si alloys used for automobile body sheet, Cu is added as a quaternary element to improve formability,^[74] in which Q phase coexists with β (Mg₂Si) in the equilibrium state.^[75] Cu addition in Al–Mg–Si alloy generally increases the kinetics of precipitation and bake hardening properties.^[65] One explanation for this effect is the reduction of solubility of Mg₂Si by addition of Cu.^[76] Another explanation is that Cu reduces the rate of migration of Mg and Si atoms, retarding the formation of Mg–Si clusters.^[77] Recent work by Miao and Laughlin^[78] pointed out that Q' precipitate follows precipitation of β'' , but this

Fig. 13 (a) 3DAP elemental maps of Mg, Si, and Cu atoms obtained from Al–0.6Mg–1.2Si–0.4Cu alloy aged for 30 min at 175°C following preaging for 17 hr at 70°C and (b) integrated concentration depth profiles of Mg, Si, and Cu atoms calculated from the selected tetragonal region shown in (a)

Source: Reproduced with permission from Murayama et al.^[79]

occurs only in the late stage of the precipitation sequence; thus the precipitation of Q' does not appear to explain the early stage relevant to bake hardening. In order to explain the effect of Cu, Murayama et al.^[79] recently studied Cu distribution in the early aging stage of Al–0.6Mg–1.2Si–0.4Cu alloy by 3DAP in conjunction with the bake hardening conditions and reported that Cu atoms are not associated with the GP zones, but are partitioned in the β'' precipitates as shown in Fig. 13. In this 3DAP elemental map, the analysis direction is [001]. In the 3DAP elemental map, needle-shape β'' precipitates with three different orientations, i.e., [001], [010], and [100], are observed. The integral concentration depth profile obtained from the inset selected region shows that the concentrations of Si, Mg, and Cu are 25, 25, and 4 at.%, respectively. In the integrated concentration depth profile, it should be noted that Mg atoms are detected first, followed by Si atoms, then Cu atoms. This is because of the difference in the evaporation field of Mg, Si, and Cu atoms: the Mg atom has the lowest evaporation field, followed by Si and Cu atoms. As demonstrated in this example, we can determine the composition of precipitates by looking at the morphology using a 3DAP.

Al–Zn–Mg Alloys

7000 series Al–Zn–Mg based alloys are widely used high strength aluminum alloys, and their precipitation sequence is accepted as:^[80]

For alloys with Zn:Mg~1:1, the equilibrium phase is T ((Al, Zn)₄₉Mg₃2), and its metastable phase, T' , precipitates prior to the precipitation of the T phase.^[9] Since the major contributor of strengthening is η' and their density

is strongly influenced by their precursors, the compositions of the GP zones and η' have been a subject of many investigations using conventional APFIM.^[81–85] In these 1DAP investigations, a substantial amount of Al was commonly detected from the precipitate particles and the Zn:Mg ratio of the precipitates determined by 1DAP significantly deviates from the stoichiometry of η , MgZn₂. The large amount of Al in the GP zones and η' particles was initially attributed to the matrix contribution. It was thought that Al atoms were collected from the matrix when the size of precipitates is smaller than the projected size of a probe hole. In the random area analysis mode using 1DAP, it is difficult to judge whether or not atoms were corrected only within the precipitates. However, it is possible to select the analysis area exclusively from inside the precipitates using 3DAP. Nevertheless, a substantial amount of Al atoms is detected even from relatively large particles, in which matrix contribution due to the evaporation aberration effect is not expected. A typical example of a 3DAP analysis result of η' and η precipitates is shown in Fig. 14.^[86] Two precipitates are observed in this 3DAP data; the Zn:Mg ratios in these two precipitates are different. The one having the 2:1 Zn:Mg ratio is interpreted as η , and the other is η' . Although the compositions were determined from the atoms only within the precipitate, almost 40 at.% Al is detected from these precipitates. Recent 3DAP analysis results of the chemical compositions of η' and η precipitates in Al–Zn–Mg alloys by Bigot et al.^[87,88] also reported that a substantial amount of Al is incorporated in these phases and that the Zn:Mg ratio of η is not consistent with that expected from the stoichiometry of Zn₂Mg. Maloney et al.^[86] reported that the Zn:Mg ratio in equilibrium phase η is 2:1. On the other hand, the Zn:Mg ratio of the GP zones and η' lie between 1:1 and 1.5:1, and they found that there is a good correlation between the solute ratios of metastable precipitates and the nominal composition of alloys as shown in Fig. 15. This

Fig. 14 3DAP elemental map of Al-2.1Zn-1.7Mg alloy aged at 150°C for 45 hr. The concentration depth profiles calculated from the two precipitates are shown

Fig. 15 Relationship between the atomic Zn:Mg or (Zn + Cu):Mg solute ratios in the parent alloy to the corresponding solute ratios in the precipitates

Source: Reproduced with permission from Maloney et al.^[86]

suggests that the atomic ratio of metastable precipitates is influenced by the atomic ratio in the alloy. Stiller et al.^[89] also reported similar results using a 3DAP.

Gradual enrichment of solute in metastable phases while maintaining the solute ratio constant is consistent with the results obtained in Al-Mg-Si alloy,^[73] where the solute ratio of Mg:Si has a good correlation with the alloy composition. Since GP zones are highly metastable aggregates of solute atoms which are insoluble with the matrix phase, it may be reasonable that these clusters have the same atomic ratio with the alloy composition. The clusters

are formed by aggregation of nearby atoms, keeping the structure isomorphous with the matrix. Thus, their composition may be determined by the number of available atoms within the diffusion field. As aging goes on, the clusters increase the solute content, and when solute content becomes high enough to form a distinct phase, they transform structurally to a more stable phase having more stoichiometric composition. Recent 3DAP analysis results of solute clusters, GP zones, and metastable phases as well as stable phases in aluminum alloys strongly suggest this view.

Rapidly Solidified Nanocomposite Ultrahigh Strength Aluminum Alloys

A new series of nanocomposite ultrahigh strength aluminum alloys was recently produced in a laboratory scale. These are Al-based amorphous alloys containing nanocrystalline particles such as rapidly solidified Al-RE-TM alloys (RE: rare earth; TM: transition metal), which exhibit extremely high strength exceeding 1200 MPa.^[90,91] For example, Al-Y-Ni alloys containing 85 to 90at.% Al can be quenched into a fully amorphous state from melt.^[90] By annealing, nanoscale α -Al particles are uniformly dispersed in the amorphous matrix, and remarkably high tensile strength is obtained when the volume fraction of the α -Al is optimized to approximately 20%.^[92-94] The origin of the high strength was attributed to the ultrafine grain structure free of dislocations, which are presumed to be difficult to deform.^[90] However, recent investigations by Zhong et al.^[95] reported that the hardness of the α -Al/amorphous nanocomposite material is essentially the same as that of the remaining amorphous phase with the same composition; thus, they attributed the ultrahigh strength of the nanocomposite Al alloys to the solute enrichment in the remaining amorphous phase.

Figure 16 shows a TEM bright field image of $\text{Al}_{87}\text{Ni}_{10}\text{Ce}_3$ nanocrystalline alloy.^[96] Extremely fine fcc-Al particles are uniformly distributed in an amorphous matrix. A high number density of nucleation sites (either quenched in nuclei or fast homogeneous nucleation rate) and effective growth-control of the nucleated particles are required for the formation of such nanocrystalline microstructure. For the compositional characterization of these nanocrystalline materials, the atom probe technique has been demonstrated to be very effective.^[97] Figure 17a shows concentration

depth profiles obtained from a nanocrystalline $\text{Al}_{87}\text{Ni}_{10}\text{Ce}_3$ alloy. Ni and Ce atoms are rejected from the α -Al particle, and partitioned in the remaining amorphous phase.^[98] Although Ni segregation cannot be seen at the interface, Ce enrichment can be clearly seen at the α -Al/amorphous interfaces. Integral profiles of Al, Ni, and Ce atoms in the partially crystallized $\text{Al}_{87}\text{Ni}_{10}\text{Ce}_3$ alloy are shown in Fig. 17b, where the number of each solute atom is plotted as a function of the total number of detected atoms. In this diagram, the slope of the plot represents the local concentration of the alloy element, and the x axis corresponds to the depth. The location of the interface is determined from the aluminum concentration change. The local concentration of each element determined from the slope of the plot is shown in the diagram. Two distinctly different

Fig. 17 (a) Integral concentration depth profiles through an Al nanoparticles in a partially crystallized Al-10Ni-3Ce amorphous alloy, and (b) schematic presentation of the concentration depth profile deduced from (a)

Source: Reproduced with permission from Hono et al.^[98]

phases are recognized based on the aluminum concentration level. One phase contains approximately 95at.% Al and the other contains approximately 24at.% Ni and 2at.% Ce. The former phase is α -Al, and the latter is the remaining amorphous phase. Note that Ce atoms are segregated within a distance of less than ~ 3 nm (corresponding to 1000 atoms in x-axis of the integral profile) at the α /amorphous interface. The concentration profile deduced from this is schematically shown in Fig. 17c. Note that only Ce segregates at the α /amorphous interface, whereas Ni does not. This strongly suggests that the diffusivity of Ce is much slower than those of Ni and Al. In Al-TM-RE based alloys, the atomic diameter of RE elements is much larger than those of Al and TM, e.g., atomic diameter of Ce is 28% larger than those for Al and Ni. In such a case, the diffusivity of Ce is expected to be lower than those of Ni and Al by orders of magnitude. In agreement with this atom probe observation results, Allen et al.^[99] concluded that rapid diffusion field impingement that occurs as a result of the high nanocrystal density limit the growth of nanocrystals based on the kinetics analysis of the primary crystallization of Al-Y-Fe amorphous alloy. Sometimes, these fcc nanoparticles show dendritic growth depending on the composition of the alloy. Using 3DAP, it is possible to observe the morphology as well as the chemical distribution in these particles. Figure 18a shows a 3DAP map of Sm atoms in a $\text{Al}_{88}\text{Ni}_4\text{Sm}_8$ rapidly solidified and crystallized alloy.^[100] Sm depleted primary crystal is clearly observed. From the elemental map, local composition is calculated, then an isoconcentration surface having local composition of 100 at.% Al can be drawn as shown in Fig. 18b. This clearly shows the dendritic morphology of

the Al primary crystal. This analysis has shown that Ni and Sm atoms were almost completely rejected from the Al primary crystal.

A different type of nanocomposite microstructure composed of nanoscale amorphous particles dispersed in relatively large crystalline grains is obtained by directly quenching Al-V-TM (TM = Fe, Co, or Ni) or Al-TM-RE melt with an Al concentration of over 90at.%.^[101–103] These include high-strength Al-based alloys consisting of a nanoscale mixture of α -Al and amorphous phases or a mixture of α -Al, amorphous, and icosahedral phases in Al-Mn-Ce, Al-Mn-Ln (Ln: Lanthanide metals), and Al-Cr-Co-Ce systems. For example, Inoue et al.^[104] reported that the tensile strength of an as-melt-spun $\text{Al}_{94}\text{V}_4\text{Fe}_2$ alloy is as high as 1390 MPa. In $\text{Al}_{94}\text{V}_4\text{Fe}_2$ alloy, when the cooling rate is not sufficiently high, i.e., when wheel surface velocity is lower than 30 m/sec, nanoscale icosahedral phase particles are formed during rapid solidification,^[104] but the microstructure of the rapidly solidified ribbon processed at a wheel surface velocity of 40 m/sec is composed of a nanoscale amorphous phase trapped within the dendritic α -Al grains, and such alloy exhibits a tensile strength of 1400 MPa.^[105] Humphreys et al.^[106,107] also studied the same alloy, and reported strong solute partitioning to an icosahedral phase formed at a lower cooling rate. The nanocomposite microstructure of $\text{Al}_{94.5}\text{Cr}_3\text{Co}_{1.5}\text{Ce}_1$ ultrahigh strength rapidly solidified alloy^[108] was also studied by 3DAP.

CONCLUDING REMARKS

Since the microstructure of alloys significantly influences mechanical and functional properties, controlling the microstructure is the key to optimize materials properties. It is commonly observed that some trace element additions drastically change materials performance. In many cases, even the presence of clusters of a few solute atoms drastically changes properties, as often seen in many industrial age-hardenable aluminum alloys. Therefore, it is very important to characterize the distribution of solute atoms in less than a nanometer scale dimension. Although the atom probe technique has various limitations, it has demonstrated a really unique and powerful capability of characterizing the local chemical compositions of solute clusters and nanoscale particles that are commonly observed in age-hardenable aluminum alloys. In particular, the 3DAP technique gives three-dimensional mapping of all alloying elements in a real space with a near atomic resolution. This method does not have any restriction in analyzing nanoscale particles embedded in a matrix phase; thus this is probably the most suitable technique for characterizing the compositions of nanoscale precipitates or clusters that are often seen in various commercial aluminum alloys.

INTRODUCTION

The Bayer process consists of the extraction of alumina from bauxite, and it represents 90% of alumina production. It is the largest pressure leaching operation worldwide regarding tonnage. The annual transformation of bauxite is shown in Fig. 1,^[1] where a dramatic increase from the 1890 to 1910 and a continuous steady increase through the decades can be observed. In 2014, the bauxite mine production worldwide was 234 million tons.^[2]

The process for the production of alumina was discovered in 1888 by Karl Josef Bayer, which, in conjunction with the Hall–Héroult process, provided the basis of the modern process of aluminum production.^[1] Whereas the Hall–Héroult process is the reduction of alumina (Al_2O_3) to aluminum by electrolysis, the Bayer process is a process in which Al_2O_3 is produced from bauxite through a pressure leaching operation using sodium hydroxide solution. This aluminum hydroxide is calcined to obtain pure alumina, which is used in the electrolysis process to produce primary aluminum (see Fig. 2).

Large amounts of bauxite are required in the production of primary aluminum. For each tonne of aluminum produced, about 2 tonnes of alumina is required, which is produced from 4 tonnes of bauxite, and 2 tonnes of hazardous waste called bauxite residue or red mud is produced.^[3] The Bayer process involves four main steps: digestion, settling, precipitation, and calcination. First, the bauxite is digested with caustic soda, also called the leaching of bauxite; during this process, the alumina is dissolved in sodium hydroxide forming hydroxide aluminate, and the insoluble particles form a red mud. After this step, bauxite residue is separated from the aluminum-containing liquor by a process known as settling or clarification. Then, a precipitation process of the pure aluminum hydroxide from the solution is carried out. Finally, a calcination step of this hydroxide is carried out at about 1000°C to obtain >99% pure alumina. Prior to these steps of the Bayer process, the bauxite needs to be crushed and ground to small particles. A general schema of the Bayer process

in the production of primary aluminum is displayed in Fig. 3.^[1,4]

DIGESTION OR LEACHING OF BAUXITE

The leaching process is the dissolution of solid ores, also called concentrates, in an aqueous lixiviant or leach liquor. This liquor can dissolve all the solid ores or part of them. Once the particles are dissolved, the liquor is called loaded or pregnant liquor. Crystals are formed and precipitate; then through a separation process, the desired metal and other metal compounds are extracted from the liquor.^[5]

The raw material for this process is crude bauxite ore, which is crushed or ground in ball mills. This crushed bauxite is first washed to remove all the fine particles coming mainly from the clay. After washing, the bauxite needs to be dried out to facilitate grinding. The drying is carried out in a rotary kiln at a temperature below the dehydration temperature of the corresponding aluminum hydroxides in order not to modify their solubility in Na_2O . The temperature of rapid hydration of the different aluminum hydroxides—gibbsite (aluminum trihydroxide), boehmite, and diaspor (aluminum oxyhydroxide)—is shown in Table 1.

The digestion process is held in steel autoclaves, where through the combination of heat injected with direct steam and pressure the aluminum-containing species in the ore are dissolved in sodium hydroxide, whereas particles from iron oxides, silicates, calcium carbonates, and titanium dioxides remain undissolved and are chemically filtered. The hydrated aluminum oxide is mixed with caustic soda (NaOH) in a high-temperature solution up to 240°C–270°C,^[6,7] and the reaction selectively dissolves the aluminum oxide in the solution to form aluminate liquor ($\text{Al}(\text{OH})_4^-$). In order to improve the solubility of alumina and to control phosphorus, lime (CaO) is added.^[8]

The temperature, NaOH concentration, pressure and time conditions depend on the type of bauxite being used. The ores containing diaspor and boehmite require higher temperature, higher pressure, higher concentration, and

Fig. 1 Annual processing of bauxite^[1,2]

Fig. 2 General schema of primary aluminum production

more time than the ores containing gibbsite. The operating conditions of the first two require a temperature of 180°C, a pressure of 800kPa, and a NaOH concentration in the range of 350–600 (g/L) for 2–4h, whereas the bauxites containing gibbsite are digested at 140°C, with a pressure of 400kPa and a NaOH concentration of 140 (g/L) for 1h.^[1,6] Due to this difference in the operating conditions, the processing of bauxites can be classified into high-cost (boehmite and diaspor) and low-cost (gibbsite) bauxites.^[5] As a general rule, the NaOH concentration is inversely proportional to the time required for the reaction; however, an elevated concentration will cause problems in further processes when filtering at the precipitation step and more dilution will be required; therefore, the concentration is balanced not to compromise the digestion and further steps.

The chemical reactions taking place during the dissolution or hydration of bauxites can be expressed as follows:

When the proper period is completed, a two-compound slurry is obtained consisting of a solution of sodium aluminate (NaAl_2OH) and soluble impurities, and an insoluble red mud.^[8] The impurities that are dissolved accumulate during the liquor recycling and tend to contaminate the product if the solution is not bled periodically. The principal impurities in bauxite that are eliminated in this process are Fe_2O_3 , SiO_2 , and TiO_2 . Red mud common

Fig. 3 Bayer cycle flow diagram^[1,3]

Table 1 Temperature of rapid dehydration of aluminum hydroxides^[1]

	Gibbsite	Boehmite	Diaspore
Formula	$\gamma\text{-AlO(OH)}_3$	$\gamma\text{-AlO(OH)}$	$\alpha\text{-AlO(OH)}$
$\text{Al}_2\text{O}_3\text{:H}_2\text{O}$ ratio	1:3	1:1	1:1
Temperature of rapid dehydration ($^{\circ}\text{C}$)	150	350	450
Product of dehydration	$\chi\text{-Al}_2\text{O}_3$	$\gamma\text{-Al}_2\text{O}_3$	$\alpha\text{-Al}_2\text{O}_3$

concentrations are in the range of 7%–10% SiO_2 , 40%–60% Fe_2O_3 , 5%–9% TiO_2 , 5%–9% Na_2O , and 13%–17% Al_2O_3 , and it is highly alkaline with a pH of 10–12.5.^[9,10] It can be observed that the main component of the red mud is iron oxide in the form of hematite (Fe_2O_3); this is the cause of its reddish color.

The chemical reactions that occur during the digestion process depend on the type of bauxite and its composition and can be expressed in general terms as follows:

SETTLING OR CLARIFICATION

At this step, there is a solid–liquid separation to remove the residues of silicates and ferric oxides from the aluminum-containing liquor near its boiling point. The autoclaves have flash tanks connected with heat exchangers where the slurry is cooled to 100°C and heat is recovered in low-pressure steam; also the evaporation of water increases

the concentration of the solution. This solution is filtered or clarified through gravity settling, decantation, or a wet cyclone to carry away coarse sand particles. The term sand is used because these particles consist mainly of silica. During the settling process, some flocculation agents are added to enhance the coalescence of these undesired particles. The properties of common iron oxides present in the slurry-like goethite ($\alpha\text{-FeO(OH)}$) and hematite ($\alpha\text{-Fe}_2\text{O}_3$) determine the effectiveness of the flocculants.^[6]

PRECIPITATION OF ALUMINUM HYDROXIDE

The precipitation step is the core of the process because at this step aluminum hydroxide is recovered from the liquor reverting the initial dissolution step now that the liquor has been filtered from the undesired particles. The clear liquor of hot concentrated sodium aluminate 2NaAlO_2 is cooled slowly, and aluminum hydroxide precipitates from the saturated solution when additional aluminum hydroxide crystals are seeded to promote nucleation sites and further crystal growth. Typically, the nucleation of precipitates can be observed in the first 30 min after the seed is added into the solution. On the other hand, if no seed is added, precipitation is not observed even after several days.^[6,11] The seed contains a large excess of aluminum hydroxide in the

solution. The hydroxide ions unbalance the equilibrium and promote nucleation and growth of crystals.

The pregnant liquor is cooled to 25°C and, in conjunction with the seeds, is stirred to allow the crystal growth. Alumina crystals of different sizes are produced during the 30 h of precipitation, while the temperature, seed rate, and caustic soda concentration are carefully controlled to obtain the desired crystals size. After precipitation, the slurry is left to settle, the fine particles are removed and recycled to be used as new seed, and the coarse crystals are filtered and washed. The crystals are separated according to their size in classification tanks. The coarser particles in the first classification tank are the ones that will be used in the calcination step, whereas intermediate-size and fine-grained crystals are washed and recycled to the precipitation tanks to act as seeds.

CALCINATION OF HYDROXIDE

Finally, to obtain alumina from hydroxide, a calcination step is performed in rotary kilns or in fluidized beds to dehydrate the aluminum hydrate crystals, and the liquor evaporates and it is recycled for leaching. The calcination can be expressed as follows:

where aluminum hydroxide is heated to about 1000°C and the product is 99.9% pure alumina.

ENVIRONMENTAL ISSUES

During the production of alumina from bauxite, a considerable amount of bauxite residue or red mud is produced and has to be disposed and stored. The annual amount of residue is more than 120 million tonnes and keeps increasing, whereas the bauxite residue grows 1 billion tonnes in the first 90 years after the Bayer process was discovered and increases to 2 billion tonnes in only 15 years from 1985 to 2000.^[12] The red mud is toxic, which represents a serious danger to the environment. The disposal methods used are marine discharge, where the residue is transported through a pipeline and disposed in the ocean; lagooning, by depositing the residue in natural depressions or dams; and dry stacking method.

All methods represent different environmental problems. The marine discharge method is less expensive and does not require land for storage; however, it covers the seabed, destroys the ecosystem, and releases toxic metals to the ocean. In the lagooning method, the slurry is

disposed directly with no need of additional processing and pollution by dust is minimized, but the disadvantage is that massive areas of land are needed. The lagoons with hazard materials represent a risk for humans and wildlife. Besides, there has to be an expensive engineering in the planning and operation of these lagoons in order to prevent leaking and catastrophic failures.

Currently, the preferred disposal method is the dry stacking method. In this method, different from the lagooning method, the land required for the storage is reduced, the risk for leaking is also reduced, the hazard materials are not exposed, and some solids are recovered for reuse. The disadvantage of this method is that large areas of land are needed.

CONCLUSION

The Bayer process is an extractive process where 99% pure alumina is obtained from bauxite. The general rule is that for each tonne of alumina, 2 tonnes of bauxite is required; the quantities might vary depending on the type of bauxite and the operating conditions. The three principal bauxites encountered are gibbsite, boehmite, and diaspor. The process involves the extraction of alumina (Al_2O_3) from bauxite through a series of processes that can be summarized as the bauxite preparation with crushing and grinding, digestion, settling, filtration and washing, precipitation, and calcination. The bauxite is put in caustic soda (NaOH), which dissolves certain species of bauxite and forms a liquor with dissolved and undissolved particles. The undissolved particles mainly from iron oxides, titanium oxides, and silica are filtered and washed. The pregnant liquor is seed with additional aluminum hydroxides (gibbsite) to promote nuclei for precipitation. Aluminum hydroxide crystals are formed and grow, and when they are large enough, they are filtered. These crystals are placed in a rotary kiln at 1000°C in the calcination step to dehydrate them. The result is 99% pure alumina (the principal product) and red mud or bauxite residue (waste). The Bayer process produces large amounts of bauxite residue that are disposed in lagoons designed for this purpose, by dry stacking or by direct marine disposal; the last is being prohibited due to the environmental damage to the seabed and uncontrolled release of toxic substances to the ocean.

Brazing Aluminum in Low Vacuum

B. N. Perevezentsev, N. M. Sokolova, and G. A. Telitsyna

Tolyatti Polytechnic, Togliatti, Russia

Abstract

The technology of vacuum brazing components of aluminium and its alloys requires a high vacuum (residual pressure $p_0 = 10^{-2} - 10^{-3}$ Pa) and the introduction of an evaporation getter – magnesium. This requires expensive special equipment with a relatively low productivity even in the presence of multi-chamber continuous furnaces. In addition, it is necessary to clean the chamber and other sections of the vacuum system often to remove the condensate of magnesium and its oxides, with partial dismantling of the furnace. In this article, the authors present the results of investigations into the evaporation of magnesium, the interaction of its vapors with AMts alloy and the special features of formation of brazed joints under low vacuum conditions.

Keywords: Defects; Degreasing; Fluxless brazing; Heat exchanger; Pastes.

The technology of vacuum brazing components of aluminium and its alloys requires a high vacuum (residual pressure $p_0 = 10^{-2} - 10^{-3}$ Pa) and the introduction of an evaporation getter – magnesium.^[1,2] This requires expensive special equipment with a relatively low productivity even in the presence of multi-chamber continuous furnaces. In addition, it is necessary to clean the chamber and other sections of the vacuum system often to remove the condensate of magnesium and its oxides, with partial dismantling of the furnace.

In Russia, brazing is carried out in periodic action vacuum furnaces because no Russian multi-chamber furnaces are available. Therefore, it is important to develop a technology of fluxless brazing which could be carried out in simpler equipment. One of the variants of this technology for small series production could be brazing in low vacuum. The Institute has carried out a large number of investigations to realise such a process (Author's cert No. 1511033, USSR).^[3]

The transition to low vacuum is possible because of the use of an auxiliary container with a gate sealed with titanium sponge and with magnesium vapours introduced from a charge placed in the gate below the sponge. Stable wetting is ensured at a magnesium charge of $P \geq 0.007$ g/dm³ and p_0 10 Pa. An increase of the magnesium charge and a reduction of the residual pressure in relation to these values have only a slight effect on wetting.

In this article, the authors present the results of investigations into the evaporation of magnesium, the interaction of its vapours with AMts alloy and the special features of formation of brazed joints under low vacuum conditions.

The investigations were carried out in special equipment consisting of a split container with a cold wall, a vacuum system enabling a residual pressure in the container of

50–1 Pa to be produced and regulated using an inleakage device, and an SNOL heating furnace.

The variation of residual pressure during the thermal cycle of brazing is shown in Fig. 1. The increase of pressure during heating is associated with the release of adsorbed gases, and the reduction of the residual pressure below the initial value observed from 500°C – with the start of the operation of the titanium sponge as a getter.

Evaporation of the magnesium was examined on bend specimens in the form of bars of conventional magnesium. The specimens were heated to 580–620°C with holding for 0–15 min, p_0 prior to loading was 9–11 Pa, during holding 1–2 Pa. Evaporation was evaluated on the basis of the variation of the mass related to the unit surface area (Fig. 2).

Active evaporation of magnesium at this residual pressure was already observed during heating and depended in a linear manner on holding time. When the temperature was increased from 580 to 600°C the amount of evaporated magnesium greatly increased. A further increase of temperature to 620°C had no significant effect on magnesium evaporation. These dependences are in agreement with the data on the effect of temperature on the pressure of saturated magnesium vapours.

Visual examination of the specimens after heating showed that evaporation takes place from a small number of local areas and, for this reason, evaporation of magnesium was then estimated from the mass loss of the specimen disregarding the area of the evaporation surface. Figure 3 shows the dependences of the amount of evaporated magnesium on the charge mass. The scatter of the data is explained by the variable amount of areas of local evaporation.

In addition to wetting, the filling of gaps and the quality of formation of brazed joints when brazing in low

Fig. 1 Graph of variation of p_0 during heating and holding at brazing temperature T_b

Fig. 2 Evaporation kinetics of magnesium in low vacuum ($p_0 = 5-10$ Pa) at 580 (1), 600 (2) and 620 (3) °C

Fig. 3 Dependence of amount of evaporated vacuum on mass of the magnesium charge at $p_0 = 1-5$ Pa

vacuum was examined. Two types of specimens were studied: specimens enabling clamping of the brazed surfaces during assembly and brazing (specimens of alternating and corrugated sheets of AMTs alloy simulating the element of plate-finned heat exchangers); specimens with a joining gap (specimens consisting of a flat sheet and a bar $3 \times 5 \times 30$ mm in size made of AMTs alloy)

The specimens of the first type were brazed with AKD-12S powder brazing alloy (particle size $65-160 \mu\text{m}$), those of the second type were brazed using dense blanks cut out from eutectic silumin sheets and with paste prepared from AKD-12S powder and a binder based on TBM-6 copolymer with an addition of a plasticizing agent.

Prior to brazing, the specimens, including the blanks of the dense brazing alloy, were degreased with acetal and etched in a reagent (40% HF; 20% HNO_3 ; 40% H_2O), rinsed with distilled water and dried. The powder brazing alloy was deposited on the tips of the corrugations in the form of a single layer by consecutive deposition of the previously mentioned binder and the powder of the brazing alloy. Tight compression of the sheets to the corrugated interlayer was ensured using a clamp. The dense brazing alloy and the brazing alloy in the form of paste were placed alongside with a gap which was varied from 0 to 0.1 mm. The specimens were placed inside an auxiliary container and magnesium (calculated amount 0.007 g/litre) was placed in the gate of an auxiliary container under a titanium sponge. The specimens were placed in a vacuum container at $p_0 < 10$ Pa, $T_b = 605 \pm 5^\circ\text{C}$, holding time 5 min.

The specimens of the first type were characterised by the formation of brazed joints with uniform fillets along the entire length of the corrugation and in sections where small gaps (up to 0.05 mm) remained after assembly. No lack of fusion or erosion visible under visual examination were found.

In the specimens of the second type using the dense brazing alloy, examination showed a typical defect: increased reversed fillet and a reduced size of the fillet or its complete absence, sometimes with lack of brazing defects at a depth of 1 mm, on the site on which the brazing alloy was placed (Figs. 4 and 5). External examination of the specimens showed that after melting, the brazing alloy spreads on the sheet along the bar to its edges and fills the gap from the side of the ends and from the reverse side. This can be explained by the fact that the brazing alloy screens the gap against magnesium vapours and delays adsorbed oxidation components of the atmosphere. Making the brazing alloy zigzag shaped in order to reduce the screening effect enabled high-quality brazed joints to be produced with uniform fillets (Fig. 6).

When using a brazing alloy in the form of paste, in addition to the above mentioned special feature the quality of the powder determined by the production technology is important. The particles of the powder which were produced in the first half of the Eighties showed, despite the relatively long period of storage, efficient melting

Fig. 4 Fillet of a reduced size in area where the brazing alloy was placed

Fig. 5 A lack of brazing defect in the area where the brazing alloy was placed

Fig. 6 Normal fillet in the area of placing the zigzag-shaped brazing alloy

together in heating by the method described previously. They wetted efficiently the AMts alloy by flowing into the gap, if screening of the gap is prevented when distributing the paste (for example, discrete portions are placed).

The particles of the powder produced at the IrkAZ plant do not melt together and, consequently, this powder is not suitable for preparing the paste.

CONCLUSIONS

1. When heating in vacuum with a residual pressure < 10 Pa and using an auxiliary container, the active evaporation of magnesium is accompanied by its interaction with the brazed metal. This results in almost complete wetting of the AMts alloy by the eutectic silumin. The mass of the magnesium charge is 0.007 g/litre of the volume of the auxiliary container.
2. When brazing joints designed in such a manner that the brazed surfaces can be clamped during brazing, it is convenient to use the powder brazing alloy and deposit in the form of a single layer on one of the brazed surfaces.
3. When brazing joints with a gap, it is necessary to distribute the brazing alloy around the gap taking into account special features of filling (screening phenomenon) – use the brazing alloy in zigzag form.
4. The possibility of using the brazing alloy in the form of paste depends on the quality of the powder, which is determined by its preparation technology.
5. The results make it possible to develop technological recommendations for brazing plate-finned heat exchangers and other components of aluminium alloys in low vacuum. The application of these measures greatly simplifies the design of equipment for vacuum brazing and increases the productivity, whilst retaining a high quality of brazed joints.

Brazing of Aluminum Alloys

Y. Sugiyama

Technical Laboratory, Sumitomo Metal Industries

Abstract

This article gives an outline of the features that different brazing methods and materials share in common, and discusses the mechanism, materials, special features and conditioning factors of vacuum brazing in particular.

Keywords: Brazeability; Brazeable alloys; Diffusion; Equilibrium diagram; Filler metal; Flux; SAG resistance.

Aluminium and its alloys (subsequently all called aluminium alloys) have a strong and stable oxide film on their surface which impedes wetting by molten solder. Because of this it was customary, before the advent of so-called fluxless brazing methods, such as brazing in a nitrogen gas atmosphere or vacuum brazing, to use a chemically active flux containing chlorides such as NaCl, KCl, LiCl, *etc* and also a small amount of fluoride, so as to facilitate wetting by molten braze and to prevent oxidation.

A drawback of brazing in which this kind of flux was used (referred to below simply as ‘flux brazing’), was that it necessitated the complete removal of flux residue, which would otherwise have an adverse effect on the corrosion resistance of the joint after brazing; and the cleaning operation and the treatment of the waste liquor required much planning and investment.

Because of their good thermal conductivity and superior corrosion resistance, aluminium alloys have long been used for heat exchangers. Often, in heat exchangers, a brazing sheet is used, with one or both sides of the core material clad with a skin of brazing filler metal, in combination with bare material, and brazing is used for assembling these.

Following developments in the automobile industry, the applications of aluminium alloys have been constantly expanding, from air conditioning apparatus such as condensers and evaporators to (most recently) radiators. Meanwhile, new brazing methods such as fluxless vacuum brazing and nitrogen atmosphere brazing, have been brought in to supplement the conventional flux furnace brazing and immersion brazing, and with the developments in the alloy field, have come to be widely used, especially in the assembly of heat exchangers.

This article gives an outline of the features that different brazing methods and materials share in common, and

discusses the mechanism, materials, special features and conditioning factors of vacuum brazing in particular.

BRAZING METHODS

The methods of flux brazing of aluminium alloys can be broadly divided as follows (the list is not exclusive), principally according to the means of heating used:

1. Torch brazing.
2. Furnace brazing.
3. (Flux) immersion brazing.
4. Induction brazing.

Many new methods of flux vacuum brazing have been developed, each with its own code and registered trademark, and associated with a particular company,^[1–4] no ‘neutral’ terms have yet been defined, and it is not easy to arrive at a just and fair classification.

Below is a classification of the methods of brazing in industrial use, particularly those used for the brazing of heat exchangers, according to whether or not flux is used. As a furnace is used in all methods, they are all within the broadly defined category ‘furnace brazing’; but the expression is now generally used as defined below.

1. Furnace brazing (narrow definition)
The use of a NaCl-KCl-LiCl flux in dry air.
2. Immersion brazing
Immersion of the material to be brazed in molten NaCl-KCl-LiCl flux.
3. Vacuum brazing
Flux brazing carried out in a vacuum (generally 10^{-5} Torr level). Usually a small amount of Mg is added to the Al-Si brazing filler metal.^[1]

4. Nitrogen atmosphere brazing

There are two kinds:

- a. Flux brazing, in which small amounts of special elements, such as Bi, are added to the brazing filler metal.^[2]
- b. That in which non-corrosive KF-AIF_3 flux (of composition in the vicinity of the eutectic point of $\text{KAIF}_4/\text{K}_3\text{AIF}_6$) is used. This flux may be prepared either by melting, or by mixture of the raw materials in powder form.

These brazing methods each have their merits and drawbacks, no single one can be declared the definitive method. On the other hand, the plant and equipment needed in each case involves considerable costs and once the plant has been installed, changing to another method is not easy. Thorough consideration must therefore be given to the selection of the method to be used. It must also be borne in mind that new brazing methods are often protected by patents.

The methods currently used for structures such as heat exchangers are those which do not employ chemically active flux, *i.e.* those which do not necessitate cleansing treatment after brazing, or nitrogen atmosphere brazing, using non-corrosive flux.

Brazing may also be classified according to the method by which the filler metal is fed to the joint part, but in brazing aluminium alloys a brazing sheet peculiar to aluminium alloys is used for preference, and this plays a major part in the use of aluminium alloys for brazed structures. Face-fed brazing and preplaced brazing alloys are mainly used for torch brazing, with NaCl-KCl-LiCl flux, with the latter being employed in furnace and immersion brazing, when a brazing sheet cannot be used. When preplacing is used, good wetting of the molten braze is not usually obtained.

THE BRAZEABILITY OF ALUMINIUM ALLOYS

In Japan, terms such as brazing, soldering, hard solder, soft solder, *etc* are not clearly defined, and confusion can arise in regard to these methods of joining materials. Here, following the usage of the AWS (USA), I propose to differentiate between brazing and soldering. (We are considering methods of joining in which molten metal of a lower melting point than the base metal is supplied to the joint.) The operation in which the temperature at which wetting is obtained is above 427°C (800°F), is termed 'brazing', and the operation in which the temperature is below this figure is termed 'soldering'.

From the point of view of brazing, aluminium alloys have the following properties, compared with other industrial metal materials:

- High thermal conductivity.
- Easy oxidation.
- Large thermal expansion coefficient.
- Colour does not change with temperature change.

Their brazeability is controlled mainly by the hard, dense surface film, the type of alloy, and in particular the melting temperature. This is because the melting point of aluminium itself is low, and because aluminium alloys are used for the filler metal too, unlike the fillers used for most industrial metals.

Oxide Film, Flux and Atmosphere

The thickness of the oxide film formed on the surface of aluminium as soon as it is exposed to the air in a perfectly clean state is of the order of $45\text{\AA}$ thick at room temperature; but when it is heated for a prolonged period to $500\text{--}600^\circ\text{C}$, the film grows to $1000\text{--}2000\text{\AA}$, and its melting point is high – approximately 2000°C , compared with that of aluminium (600°C).

For this reason, in brazing in air in general, flux is used to prevent the oxide film from being broken and 'lifted' and thus exposing the pure base metal. The flux traditionally used consists of NaCl-KCl-LiCl with small amounts of fluorides such as NaF and AlF_3 added. In furnace brazing, the method of atmosphere control, using dry air, has been introduced in order to reduce the amount of expensive flux used.^[5]

Another innovation is the attempt to improve corrosion resistance by adding a small amount of ZnCl_2 to the flux, and distributing the substituted Zn to the joint. A difficulty here is that when this kind of flux is used in furnace brazing, the residual flux has to be cleaned away after brazing if corrosion is to be prevented.

The flux brazing described above, and the method whereby KF-AIF_3 flux is used in a nitrogen atmosphere, in so far as they do not require cleaning after brazing to clean away the residue of the flux, have probably contributed a good deal to the development of techniques for brazing aluminium alloys.

Types of Brazing Filler Metal

Alloys in which Si in the main, but also Cu, Zn and other elements are added to aluminium of industrial purity in order to lower the melting point and give it the required physical and chemical properties, are used as brazing alloys for use with aluminium alloys. As can be seen from the Al-Si equilibrium diagram of Fig. 1, Si lowers the melting point of aluminium. However, ductility is lowered as the amount of Si is increased.

Copper and Zn also lower the melting point of the alloy; but in general these elements weaken the corrosion resistance of the joint. If a small amount of Mg is added to Al-Si filler metal, flux brazing at the industrial level becomes possible (see later).

In Japan aluminium alloy brazing filler metal and brazing sheets are specified in JIS Z 3263 1980 (Tables 1–3).^[6] Alloy 4245 (Al-10%Si-4%Cu-10%Zn, which is not mentioned in the JIS) has a solid phase temperature of 516°C ,

Fig. 1 Equilibrium diagram of Al-Si system

and a brazing temperature of 549–571°C, the lowest brazing temperature of the standard filler metals.

For reference, the following alloys are established in the USA for vacuum brazing (Aluminium Association),^[7] 4004 and 4104; (AWS),^[8] BA1Si-7 (4004) and BA1Si-8 (Al-12%Si-1.5%Mg). In the UK, in addition to 4004, 4104 (Al-10%Si-1.5%Mg-0.1%Bi) is established.^[9]

JIS Z 3263 is reconsidered and amended as necessary, principally with reference to US standards. Among filler metals for vacuum brazing, the inclusion of those containing a minute amount of Bi has so far been seen as premature.

Brazeable Alloys

As aluminium alloys are used for the brazing of aluminium alloys, brazeability is affected by the melting temperature

of the base metal alloy. In general, pure aluminium, Al-Mn, Al-Mg with a small Mg content, and Al-Mg-Si alloys are comparatively easy to braze. But with Al-Cu, Al-Mg and Al-Zn-Mg-(Cu) alloys with an Mg content of more than 2.5%, because their melting temperature is relatively low and the molten brazing alloy is liable to diffuse over and penetrate into the base metal, brazing is not so easy. The brazeability of aluminium alloys is shown in Table 4.^[10]

Cast aluminium alloys, containing numerous elements, usually have a low melting point; and those which are brazeable are restricted to Al-Zn-Mg-(Cu) and Al-Si-(Mg) alloys. For the latter, a low melting point brazing filler metal such as 4245, in which other elements have been added to Al-Si, must be used.

Properties Required in Base Metal

A first precondition for brazing is that the melting temperature of the base metal should be higher than that of the filler metal. The type of alloy is therefore restricted, but the base metal must also have the other properties outlined below. These properties are interconnected; so when it comes to actual use, an overall assessment and judgement of these properties as a whole is needed.

Strength

A high level of strength is desirable in brazeable alloys. In order to enhance their strength, aluminium alloys are refined by cold working, heat treatment and the like, and it must be borne in mind that the base metal is affected by heating during brazing.

Note:

¹Analysis of the other elements is carried out only when their presence is known beforehand, or when there are signs, in the course of the normal analysis, that they are in excess of the prescribed limit.

What this means is that in the case of work-hardened alloys, after brazing, the strength of the base metal is reduced to or below the level of its soft equivalent; in that of heat-treated alloys, while the effect will differ according to the speed of cooling after brazing, in the event of slow cooling the strength of the base metal will likewise fall to the level of its soft equivalent, and the effect of heat treatment will be lost.

In the latter case, the strength can be recovered, by rapid cooling after brazing and by ageing. Alloy 6951 is a typical example, while a point in favour of Al-Zn-Mg alloys such as 7005, in which the Mg content is comparatively small, is that they have a low susceptibility to quench hardening, together with a property of natural age-hardening.

The strength of the braze (Al-Si) forming the joint will differ according to the amount of Si and the speed of solidification, but it is higher than that of the brazeable soft alloys. Consequently, in tensile shear tests of brazed joints (lap joints), rupture occurs in the base metal, as indicated by Table 5.^[10]

Sag resistance

The strength of aluminium alloys at high temperature is in general low. In the brazing of various types of heat exchangers, the material (which should be thin and light), the weight of the assembly itself and of the jigs, can cause waviness or sagging. Figure 2 shows (a rather old

**Fig. 2** Sag after 615°C×30min heating in air of 0.16mm thickness A3003P-H and brazing sheet (cladding rate: 1 side 15%), ×0.75

This same tendency was apparent when the heating time was 5–15min. It was tested by placing circular sheets 40mm in diameter, horizontally on a vertical rod at 25mm intervals, with spacers between. It was found that the extent of sag differed between bare material and brazing sheet, and between brazing sheets depending on the type of cladding.

Sag is influenced not only by the high temperature strength of the base metal aluminium itself and the thickness of the sheet, but also by the degree of ease/difficulty with which the Si in the filler metal and the molten braze penetrates into the base metal or core material, and by the brazing conditions.

Diffusion of Si or Penetration of Molten Braze

Obviously the braze required to form the joint should remain in the joint area until the completion of brazing. However, in the brazing of aluminium alloys in which brazing sheet and bare material are both used, and in particular, the case of large structures, where a long brazing cycle including preheating is involved, the braze in the joint area may be insufficient to enable a good joint to be obtained.

In the brazing sheet, the core material and the cladding being joined metallurgically, the Si in the cladding (filler metal) is liable to diffuse into the core material during the process of preheating and heating-up in the brazing cycle; in extreme cases, it may even happen that the cladding does not function as filler metal when the brazing temperature has been reached. Also, in that part of the core material which is close to the boundary between cladding and core material, the composition of the core material may be affected by diffused Si.

Thus far it has been a question of diffusion between solids; but when the cladding reaches melting temperature, liquid-solid diffusion may lead to the molten braze penetrating the core material, which if it goes too far can result in erosion. This behaviour is not confined to brazing sheets; the same thing applies to molten braze and bare material which is wetted.

On a previous occasion my colleagues and I studied the relationship between molten braze and core material grain size in immersion brazing,^[11] using a standard brazing

sheet consisting of 3003 core material and 4343 cladding. This study demonstrated that the finer the grain size of the core material, the easier it is for the molten braze to diffuse into the core material.

Since diffusion between solids is more rapid when the grain size is fine, in brazing where a brazing sheet is used it is desirable, if the diffusion of the Si in the cladding to the core material and the penetration of the molten braze into the core material are both to be checked, that the grain size of the core material should be on the large side, within the required range. In a brazing cycle the materials involved go through a whole 'thermal history', from normal temperature through to completion of brazing, and in many cases the component materials will have undergone cold working, so that these two aspects have to be borne in mind when considering the question of controlling grain size.

For example, line materials which have undergone cold working, whether brazing sheet or bare material, will recrystallise in the process of reaching the brazing temperature, and depending on the extent to which they have been worked, their grain size will become smaller, with the result that when this part comes into contact with molten braze, erosion of the base metal is accelerated. This effect of grain size is not marked when the brazing cycle is short. The important thing is to close the routes by which diffusion takes place (grain boundaries and sub-boundaries, where diffusion has precedence); and there will no doubt continue to be further metallurgical studies of this aspect.

The following are the other factors affecting the diffusion of Si and penetration of molten braze, apart from grain size as discussed above.

1. Heating time and temperature

Within the required range, the temperature should be as low, and the period as short, as possible.

2. Alloy elements

3004 is more liable to be penetrated by molten braze than 3003, and 6061 than 6063 and 6951. This is mainly because of the Mg content. In the vacuum brazing ($582\sim 610^{\circ}\text{C} \times 5\sim 10\text{min}$) of these alloys, a concentration of Si, Mg and Cu was observed in the grain boundary penetration areas of the 6951 core material, while in 3004 the concentration was of Si, and the Cu and Mg were only slightly higher than in the base metal; and it has been stated, on the basis of these observations, that Cu promotes grain boundary penetration, and delays the penetration of Al-Mg compounds.^[12] However, when the author studied the effect of adding Mg at different levels to the 3000 series alloys, he found that the increase in strength was controlled by erosion resulting from the increase in the Mg content.

3. Atmosphere

There does not appear to have been any report of quantitative results, but in one case of a brazing sheet for vacuum brazing consisting of a 6951 alloy core

and alloy cladding of Al-9.5%Si-1.5%Mn-0.8%Bi, grain boundary penetration was greater in a vacuum than in a nitrogen atmosphere. The temperature-dependence was about the same in both cases.^[12]

4. Sheet thickness

It goes without saying that the thinner the sheet, the greater is the effect of grain boundary penetration on the intrinsic properties of the base metal (core material).

Corrosion Resistance

In many cases, structures assembled by brazing are surface-treated (by painting, *etc*), according to the use for which they are intended. Naturally, however, their component parts are themselves required to have good resistance to corrosion. Fortunately, alloys of the 1000, 3000 and 6000 series, which are generally used for brazing, belong (even within the many aluminium alloys) to the highly corrosion-resistant category.

When automobile heat exchangers, for example, which are exposed to a severely corrosive environment, are assembled from the same alloy, their corrosion resistance is still inadequate; and nowadays, in order to prolong the life of the tubes through which the coolant passes, these tubes are protected with fins, which constitute a sacrificial anode. In this case, the tubes and fins co-exist, with fillets of braze between them, in the corrosive environment. Also, bearing in mind the metallurgical behaviour (such as diffusion) associated with the brazing cycle, proposals have been made, and applied, for the assembly of different types of alloy.

The water tubes of radiators are usually manufactured from hoops of brazed sheet by high frequency induction welding; triple 'tubes' may be used, consisting, for example, of a core of 3003 alloy, clad with an outer facing of filler alloy and an inner facing of 7072 alloy.

Loss of Alloy Elements

Some sublimation or loss by evaporation of the Mg and Zn which are added to improve the strength and corrosion resistance of an alloy is unavoidable in vacuum brazing, since the vapour pressure is so high. Inevitably, therefore, when alloys are used to which these elements have been added, there is a need for some countermeasure such as atmosphere control, by which, in anticipation of their loss, an extra amount is added. The addition of Li has been proposed to control the evaporation of Mg; but this does not appear to have been applied in practice yet. These evaporated elements, in the form of oxides, accumulate in the low-temperature part of the furnace, causing contamination and impairing the purity of the atmosphere.

Also, as I said earlier, in vacuum brazing, Mg is contained in the cladding (filler metal) of brazing sheets. Magnesium is added on the premise that some of it will

evaporate; but the amount should be extremely small, in view of the contamination of the furnace involved.

MECHANISM OF VACUUM BRAZING

The flux brazing of aluminium alloys has been studied for some considerable while.^[13] Vacuum flux brazing, however, originated with the basic patents taken out by the G.E. Co. of the USA in 1967 and 1968.^[14] This is a method by which brazing is carried out in the presence of Mg vapour in a vacuum or non-oxidising atmosphere.

Here, the Mg vapour was provided by Mg (alloy) powder placed in the atmosphere, together with the alloy element in the brazing sheet cladding. On the basis of these patents, Reynolds and Alcoa developed the method into a process, which in 1971 created quite a stir in the relevant journals, and attracted much attention in related fields.^[15] Studies followed of the possibility of replacing Mg by some other element, but it was concluded that the addition of Mg was indispensable, and the method as it exists today was developed.

With regard to the mechanism of the process, a variety of proposals have been put forward, in view of the fact that the success of the brazing depends on how and to what extent the oxide film covering the surface disperses when the cladding (brazing filler metal) melts in the presence of Mg. For the formation of the joint, it need hardly be said, the braze must penetrate the oxide film of both the brazing alloy itself and the base material.

As for the chemical effect, vacuum brazing can only take place when the following three formulae are fulfilled: $M + \frac{1}{2}O_2 \rightarrow MO$, $M + H_2O \rightarrow MO + H_2$ and $M + \frac{1}{3}Al_2O_3 \rightarrow MO + \frac{2}{3}Al$ (M: metal, MO: oxide). Magnesium is best as the metal, and the minimum amount required, both theoretically and experimentally, is considered to be 0.3%.^[16] The Mg functions as a getter, removing the residual oxygen and moisture in the furnace, and reduces the oxide.

Next, the structure of the oxide film is changed by the Mg, enabling brazing to take place. At above 400°C, when the Mg vaporises, the oxide film on the surface of the Al-Si-Mg cladding is modified, becoming porous. When the eutectic temperature of 551°C is reached, the molten braze passes through the pores in the film by capillary action and covers the modified oxide, until the oxide disappears. At 565°C, the braze is completely melted; at 595°C macroflow of the braze may be observed.

With cladding containing more than 1%Mg, the whole surface is covered by molten braze and the oxide disappears completely, whereas with cladding with a low Mg content is only partially covered. In the case of base material, too, vaporised Mg promotes wetting of the porous surface oxide.^[17-19]

What this modified film is, is not indicated. Another report states that the oxide film on the surface of the cladding is split during heating by the formation of σAl_2O_3 and

(probably) $MgO \cdot Al_2O_3$, but that this cannot explain the fact that when the brazing temperature has been reached the surface is metallic. The reason, the author infers, is that when the solid phase temperature is reached, all the Mg in the filler metal is sublimated, and the surface tension of the molten braze increases.^[20]

With the reduction of Al_2O_3 and the formation of MgO and $MgAl_2O_4$, since these oxides do not readily wet with molten aluminium, a metallurgical study was carried out of the structural changes that occur during brazing, and it was suggested that brazeability depends on the physical and chemical effects of the Mg in the brazing filler metal.^[21] The supposition is that at the eutectic temperature of Al-Si-Mg, which is 55°C, or at a slightly lower temperature, local initial fusion of the cladding (braze) occurs, the surface film is disrupted, and exudation of the melted eutectic crystals takes place.

In a vacuum the eutectic crystals lose Mg by evaporation, and resolidify. This is repeated until the whole surface becomes clean metal; the molten braze flows, and this surface continues to hold up to the eutectic temperature of Al-Si, at which brazing begins. Here, at above 400°C the film on the surface of the cladding is almost all MgO. The thickness of the film after a new surface has been formed by exudation at the eutectic temperature is minimal, and the growth of the oxide film at high temperature is controlled by the evaporation of Mg from the brazing filler metal and the oxidation conditions in the furnace. The thinner the film, and the lower the oxidising capability, the better will be the brazing.

With regard to physical effects, observation with an SEM revealed no striking changes up to approximately 450°C, when several points of brightness appeared on the surface of the cladding, but at the ternary eutectic temperature of Al-Si-Mg (55°C) disruption began to appear in spots, spreading over the whole surface as the temperature increased.^[22-24] The disrupted surface was jagged and uneven.

At the binary eutectic temperature of Al-Si (577°C), most of the braze had begun to melt, and the unevenness in the surface disappeared, leaving it smooth again. This observed result was not obtained with cladding not containing Mg, and there was no formation of fillets.

Such are the suggestions that have been put forward for the chemical mechanism of the effect of Mg, together with a physical counterpart involving the disruption of the oxide film; but no definitive theory has yet been established. However, the recent adoption of high-temperature SEM may well provide new information that will enable the mechanism to be elucidated.

MATERIALS FOR USE IN VACUUM BRAZING

As was stated above, in the vacuum brazing of aluminium alloys the presence of Mg vapour in the atmosphere is indispensable if wetting by the molten braze is to be obtained.

Generally, Mg is contained in the cladding (brazing filler metal) of brazing sheets, as indicated in Tables 2 and 3; but brazing may also be carried out with Mg as an alloy element in the core material or the base metal.

Again, Mg (alloy) in powder or sheet form may be placed in the furnace, separately from the object to be brazed. In this case, the Mg will be sublimated at a temperature considerably lower than the brazing temperature; and with complex assemblies no better action can be expected.^[25]

In vacuum brazing, the loss of high vapour-pressure alloy elements such as Mg and Zn that occurs as a result of evaporation in the course of the brazing cycle means that if the intended use is such that the particular features of these alloy elements are important, the amount of this loss must be taken into account beforehand.

In any case, the evaporated alloy elements will accumulate in the low-temperature parts of the furnace and impede the brazing operation. On the materials side, therefore, the current practice is to limit the amount of Mg to the minimum necessary for brazing.

Base Metal (Core Material)

Alloys that can be brazed by ordinary flux brazing methods can also be brazed in a vacuum. This is true even of the 5000 series, such as 5052, which has a comparatively high Mg content and which does not lend itself easily to flux brazing.

Examples of the use of Mg in the core material and base material, without using cladding (brazing filler metal) containing Mg are automobile radiators^[26] and evaporators^[27] which combine a brazing sheet consisting of core material of 3005 alloy (Al-1.2%Mn-0.4%Mg) and alloy cladding of Al-12%Si-0.1%Mg with alloy fin material of 5005 alloy (Al-0.8%Mg). In the latter case, when quantity production was initiated on a trial basis with component materials selected for their low Mg content, because of the frequency of the need to clean the Mg and Mg oxide adhering to the furnace and jig, it was found that batch coil softened material was superior in brazeability to continuous coil softened material, and that batch coil softened material in which the amount of Mg in the 3005 alloy core material was at the level of the upper limit was inferior to that in which it was at the median level; and the reasons for this are under study.

The Mg required for brazing must diffuse over the surface of the cladding (which has a low melting point) in the course of the brazing cycle. With sheet of good brazeability, deposited Mg_2Al_3 dissolves rapidly at the core material side of the cladding-core boundary, and the Mg released at this timely juncture reacts with the oxide in the furnace to clean the atmosphere. Here the deposit is obtained by slow cooling from the annealing temperature after cold rolling.

These results suggest that to achieve satisfactory brazing, not only must attention be given to the chemical composition of component materials, but on the materials side, an environment must be prepared which will enable the alloy elements used to exert their full effect.

Brazing Filler Metal

In flux furnace and immersion brazing, a brazing sheet with 4343 alloy for cladding is standard, but in vacuum brazing, brazing filler metal of which the Si content is 9–13% and the Mg content 1–2% is used for the cladding (Table 2). The composition of the brazing filler metal is important for the fluidity of the molten braze and for removing the effect of surface oxidation.

As the amount of Si is increased, this element lowers the melting point and increases fluidity, but the degree of erosion is also increased thereby. Magnesium, as already stated, is essential in vacuum brazing; but from the point of view of maintaining the atmosphere of the furnace, the Mg content should be kept low.

It may be of interest that in America a distinction appears to be made, in the combination of core material and cladding, between 3003/4104 as a high Mg type and 3005/revised 4047 (0.1%Mg)^[18] as a low Mg type. The Bi which is contained in 4104 in a micro-amount (0.02–0.2%) is believed to improve the workability of high-Mg solder in a low vacuum atmosphere of 10^{-3} Torr.^[28]

As for the amount of Mg in the cladding required for vacuum brazing, it has been reported that this should be at least 1%.^[19] The results of observation by high temperature SEM of the exudation of molten braze and the disruption state of the film, when cladding materials containing 9.7%Si but with differing amounts of Mg, namely 1.5% (core material: 3003), 0.7% (core material: 6063) and 0.13% (core material: 3005) suggest that the most appropriate amount of Mg is approximately 1.5%, that 0.7% is somewhat inadequate, and that 0.13% has no effect at all.

Magnesium affects the phase equilibrium state of Al-Si alloys, ternary eutectic crystals being formed in high-Mg solder at 5510 (Fig. 3).^[29] (Bi of the order of 0.1% has virtually no effect on the equilibrium state.)

For reference purposes, pure Mg is sublimated at 316–427°C,^[25] but in a brazing sheet the sublimation temperature

Fig. 3 Liquidus line of Al-Si-Mg system

of Mg is 532°C,^[28] with rapid evaporation when 551°C, the eutectic temperature of Al-Si-Mg, is reached. The speed at which this takes place depends on the heating rate.^[17]

DISTINCTIVE FEATURES OF VACUUM BRAZING

Advantages

The particular advantages of vacuum brazing may be summarised as follows.

1. Flux is not required
This is the feature to which special attention must be drawn. All the disadvantages associated with the use of flux are eliminated, with the following results:
 - a. Economies (cost of flux and supervision).
 - b. No coating of flux, no cleaning process (including waste liquor treatment).
 - c. No 'sucking in' of flux, no corrosive residue.
 - d. Greater freedom of product design.
 - e. Low grade materials can be used for jig, *etc* (no erosion or weight loss due to flux).
 - f. Improved operating environment.
2. Ease of automation and mass production.
3. Constructive use of vacuum atmosphere.
There are probably few examples to point to at the moment, but there are good prospects for the joining of aluminium and metals such as Ti which are particularly active at high temperature, or non-metallic materials (ceramic, *etc*). It is established that Al and Ti can be brazed.

Disadvantages

The following disadvantages may be mentioned:

1. Comparatively high cost of equipment.
2. Loss of the alloy elements which sublimate/evaporate easily; accumulation of the oxides of these elements in furnace, on jig, *etc*, and the need to remove these accumulations.
3. Gas cannot be used as a heating medium.

The fact that, compared with the flux methods, pre-placed brazing is not easy with vacuum brazing, may also be counted a disadvantage.

Comparison with Other Brazing Methods

With regard to the question of which is superior, vacuum brazing or the other recently developed methods touched on earlier, presupposing mass production in both cases, some degree of qualitative comparison may be made on

the basis of the methods of pretreatment, the use or otherwise of flux, plant cost, heating rate, brazing materials, *etc*. A quantitative comparison, however, involving the same products and amount of production, with only the brazing method changed, would not be easy, as a large-capacity continuous furnace would be required. In this sense, the publication of evaluations by the manufacturers of heat exchangers, working from the actual results achieved, is eagerly awaited.

FACTORS AND PROCESSES AFFECTING VACUUM BRAZING

Apart from the brazing materials discussed earlier, the main factors affecting vacuum brazing are as follows.

1. Surface state
Residues of organic matter, and an excessive film of oxides and hydroxides, on the surface of aluminium alloys have an adverse effect on brazing in general, not only on vacuum brazing. The extent to which the surface is cleaned before brazing is therefore important.
The behaviour of the surface when 3003/4004 aluminium alloy brazing sheets pretreated in different ways were heated in a vacuum has been observed by high temperature SEM.^[23] Rolling oil (10, 25, 135 mg/m²) had an adverse effect on the disruption of the film and the flow of the braze, but the extent of this effect was not great.
With regard to moisture, the effect of exposure to 100% humidity for 24 hr at 60°C was less than that of actual contact with water. Also, disruption of the film and flow of the braze were conspicuously worse in specimens subjected to preparatory oxidation by heating in air for 4hr at 475°C. When annealing is necessary before use, therefore, high temperature heating should be avoided.
Pretreatment prior to vacuum brazing will generally include degreasing with an organic degreasing agent.
2. Atmosphere
Atmosphere is usually measured as total pressure, but an important factor to be monitored in vacuum brazing is the partial pressure of impure gases such as oxygen, moisture, *etc*. Carbonic acid gas is also regarded as an impure gas in this context.^[25]
According to an experiment using automobile heat exchangers:^[25]
 1. Brazing was successful at a vacuum pressure of 2×10^{-5} Torr.
 2. When air was mixed in, reducing the pressure to 3×10^{-4} Torr, brazing faults occurred.
 3. When the vacuum pressure was reduced to 3×10^{-4} Torr by mixing in dry nitrogen at 2×10^{-5} instead of air, brazing was satisfactory.

The partial pressures of oxygen and moisture in 1 and 3 were 2×10^{-8} and 4×10^{-7} Torr respectively. Again, in an experiment simulating the brazing cycle, in which 4004/3003 alloy brazing sheets were used, the moisture in an atmosphere of below 1×10^{-4} Torr was removed; but from the point of view of reliability and safety, a level of 10^{-5} was considered appropriate.^[28]

At present, vacuum brazing is usually carried out at a level of 10^{-5} Torr.

3. Joint gap

The joint gap in vacuum brazing is generally, under good conditions, of the order of 0.05–0.1 mm. If the degree of vacuum is inferior, even stricter control is necessary, and wire contact is desirable.

There appears to be no particular restriction as regards the area of overlap, and laminated brazing is also possible. In comparison with flux brazing, in a vertically positioned joint the molten braze will tend to drip and much thought may need to be given to joint design, type of solder and cladding rate. Also, the molten braze will tend to flow, by capillary action, into any tiny groove or the like on the surface of the component materials. Advantage may be taken of this on the working surface.

4. Jigs

Stainless steel is usually used for jigs; carbon steel is also used, for small-scale production. It need hardly be said that jigs should be light, of small heat capacity, and easy to install and remove; and to avoid erosion, their construction should preferably be such that they do not come into contact with the molten braze. There is no need to wash jigs after brazing, as in the case of flux brazing; but they should be handled with care, to avoid contamination of the atmosphere.

5. Heating

When it comes to heating, what is important first of all is that there should be a uniform temperature distribution. In setting the heating cycle, consideration must be given to the reaction with gaseous impurities, the temperature gradient within the assembly, erosion, inter-diffusion between cladding and core, 'thermal history', the metallurgical behaviour of the component materials, *etc.*

In general, the heating rate should be as rapid as possible, and the brazing time short; the cooling rate too should preferably be fast. When endeavouring to obtain the desired strength with 6000 series alloys, in particular, the cooling speed must be rapid (*e.g.* faster than $17^\circ\text{C}/\text{sec}$) in order to achieve solution treatment. The desirability of a high heating rate has been confirmed by high temperature SEM.^[23]

6. Brazing processes

The following are the typical processes involved in brazing.

1. Formation of component members (cutting, forming, *etc.*): lubricants used should preferably be of a type which can easily be removed in the subsequent vapour degreasing process.
2. Preparatory cleaning of members: this generally consists of vapour degreasing only.
3. Assembly: with use of jigs as necessary.
4. Brazing: brazing in a batch-type or semi-continuous furnace.
5. Cooling: dry nitrogen, and sometimes backfill with dry air.
6. Withdrawal of assembly, inspection, surface cleaning, *etc.*

VACUUM BRAZING FURNACE

There are cold wall and hot wall types of vacuum furnace. For a vacuum furnace for the brazing of aluminium alloys, with a brazing temperature range of $580\text{--}620^\circ\text{C}$, in a degree of vacuum of $10^{-4}\text{--}10^{-6}$ Torr, a uniform temperature distribution of at least $650 \pm 5^\circ\text{C}$ is desirable. Oil rotary and diffusion pumps are used in the vacuum system.

Depending on the extent of operations, the respective heating compartments may contain a single batch oven, preheating chamber, *etc.*, with several semi-continuous heating compartments for different uses. Selection will depend on the size, shape and quantity to be produced of the assembly being brazed. The furnace must, of course, be of a construction such that matter accumulating within it can be removed without difficulty.

Batch Furnace

This is the simplest type of furnace, consisting of a single brazing oven and having a door at one or both ends. When an assembly is loaded into or withdrawn from the furnace at the beginning or end of the brazing cycle, the furnace is open to the air; and because the inside of the furnace is contaminated thereby, drawing the vacuum takes time, and long brazing cycles are required in order to obtain satisfactory brazing results. This type of furnace is therefore suited to the trial manufacture of small quantities of different types of product.

Other furnaces, also described as batch furnaces, are being introduced in which separate compartments are provided in front of and behind the heating (brazing) compartment; the former being used for the preheating of parts prior to loading into the heating compartment, and for degassing, and the latter for solidification of the molten braze and initial cooling of the assembly by dry nitrogen or air backfill. Here, a furnace in which the assembly comes to a stop, within the brazing furnace, at a particularly important part of the brazing cycle ($400^\circ\text{C} +$; the temperature distribution of the assembly is uniform, the braze melts, and the joints are formed), is termed a 'batch' furnace.

Semi-Continuous Furnace

This type of furnace is designed to prevent contamination of the atmosphere on loading/withdrawal of an assembly, and to improve productivity. It has more than one heating compartment, with loading and withdrawal compartments before and behind, each compartment being divided off by a gate-type door.

When each of these heating compartments with their associated compartments behind and in front is used as a batch furnace, then in effect this semi-continuous furnace has two or more heating compartments. When there are several heating compartments, an independent heater in each compartment provides heat up to the prescribed temperature while the assembly is being moved, which helps to increase productivity.

If one takes the figures given by one furnace manufacturer as a guide, the times taken for brazing are as follows: batch furnace, 60 min; three compartments (preheating → brazing → withdrawal), 20–40 min; four compartments (preheating → degreasing → brazing → withdrawal), 10–30 min; six compartments (preheating → degreasing → preheating → brazing → air cooling → withdrawal), 8–15 min. The degreasing referred to here is vacuum degreasing.

Figures 4 and 5 show the temperature of the assembly and the degree of vacuum in batch and semi-continuous furnaces.^[18]

Fig. 4 Schematic diagram showing temperature of assembly and degree of vacuum in batch furnace

Fig. 5 Schematic diagram showing temperature of assembly and degree of vacuum in semi-continuous furnace

APPLICATIONS OF VACUUM BRAZING

Various types of heat exchangers for automobiles are the most common product manufactured by vacuum brazing,^[30] other items include air conditioning evaporators and condensers, and oil coolers. Recently, aluminium has started to be used for radiators^[26] even in America – which lags behind Europe in this respect – and Japan too is showing interest in this development. The manufacture of microwave-related parts by this method has also been reported.^[31] These products are all comparatively small and suited to quantity production.

Even large heat exchangers of the plate fin type used in air separators, for which immersion brazing used to be thought most appropriate can now be manufactured by vacuum brazing.^[32] Honeycomb structures too, in the manufacture of which bonding agents have been used hitherto, are now being manufactured by vacuum brazing, and new uses for these structures are anticipated.

SUMMARY

The strong point of vacuum brazing, namely that it does not use flux, led to its gradual substitution for conventional flux brazing, and this in turn resulted in an expansion of the range of uses for the brazing of aluminium alloys. Research and development were then directed towards new methods of brazing, and today fluxless nitrogen atmosphere brazing, and nitrogen atmosphere brazing using non-corrosive flux, are both in operational use.

These methods all have their respective advantages and disadvantages, and at present no conclusion can be reached about which is best. New methods may well be developed as time goes on; but with so much investment in plant and equipment being involved, it is likely that for the foreseeable future existing methods will continue in parallel with any others that may be devised. Perhaps consideration will also be given to the possibility of combining the advantages of different methods. It is a fact, in any case, that the development of vacuum brazing has led to a reappraisal of techniques for the brazing of aluminium alloys, and also to an extension of our knowledge of brazing generally.

With regard to base metal for brazing, while there may be some minor improvements, it does not seem likely that we shall see any major development. Topics such as multi-laminated brazing sheets which would make the most of the special features of alloys may well be discussed and studied; but with constant pressure nowadays to reduce thickness, problems such as production control and cost will present obstacles. One area where the prospects seem good is that of linkup with the techniques of surface-refining that have witnessed such striking development in recent years.

The above discussion presented a summary of the general items common to different methods of aluminium alloy brazing, and set out the essential factors in vacuum brazing in particular.

Abstract

This paper details a systematic investigation of the formation of Al-based bulk metallic glasses, expanding on an earlier brief report.^[13] We discuss an approach for designing and predicting the best glass-forming composition in the Al–TM–RE systems, based on the atomic cluster packing model for the internal structure of the glass. The effects of additional elements in quaternary and quinary systems on the glass-forming ability and thermal stability of the glasses are also discussed. Three new compositions, $\text{Al}_{86}\text{Ni}_6\text{Y}_{4.5}\text{Co}_2\text{La}_{1.5}$, $\text{Al}_{86}\text{Ni}_7\text{Y}_5\text{Co}_1\text{La}_1$ and $\text{Al}_{86}\text{Ni}_7\text{Y}_{4.5}\text{Co}_1\text{La}_{1.5}$, are capable of forming fully glassy rods of 1 mm in diameter; their glass transition and other thermal properties are systematically characterized.

Keywords: Aluminum alloys; Bulk metallic glasses; Cluster packing model; Electronegativity.

INTRODUCTION

Aluminum-based metallic glasses represent an important family of amorphous metals, due to their desirable properties such as high specific strength, good ductility and good corrosion resistance.^[1,2] Of particular interest is their exceptional specific strength, which is twice that of conventional crystalline aluminum alloys.^[3–5] However, Al-based alloys have relatively low glass-forming ability (GFA) compared to other bulk metallic glass (BMG)-forming systems. As a result, the search for Al-rich BMGs has encountered major difficulties since the early 1990s,^[6–12] despite the large number of studies conducted. Only recently, fully glassy 1 mm Al-rich BMG rods have been obtained in Al–Ni–Y–Co–La systems by copper mold casting,^[13] based on an alloy composition design strategy from the preferable internal glass structure.^[14–16] This discovery is expected to stimulate another surge of interest in the development and applications of light-weight BMGs with unique combinations of desirable properties.

The formation of metallic glass is the result of the suppression of the crystallization process during cooling. GFA is closely related to phase selection of the glass over

all the competing crystalline phases.^[17–19] From empirical criteria,^[20,21] the best glass forming range in the phase diagram is located at compositions where the easily forming primary phases can be avoided. The experimental search for BMGs, however, requires tremendous effort and it will be advantageous to be able to predict BMG-forming compositions. Thus, a possible approach is to evaluate the stability of the internal glass structure. Recently, Miracle et al.^[22] proposed the existence of a special atomic radius ratio to choose alloying elements and design high GFA compositions. For example, the atomic size distribution plot of Al-based MGs has a concave downward shape: the atomic packing density can be increased by adjusting the radius ratio between the solute and solvent atoms to influence GFA.^[23] Hence, we propose a cluster packing protocol to design the potential BMG-forming Al alloy compositions. The important role of solute-centered quasi-equivalent clusters in multi-component Al-based metallic glasses was validated by our experimental and modeling studies.^[15,16,24]

As shown in Fig. 1, in the Al–TM–RE system, the rare earth (RE)-centered clusters and transition metal (TM)-centered clusters are coexisting. The two stable cluster

Fig. 1 Illustration of the composition design scheme using cluster stability lines in the Al–Ni–Y ternary alloy phase diagram. The green (online) star at the intersection point of the two lines is the favorable composition predicted

lines, referred to as the TM and RE stable cluster line, can then be used to estimate the structurally favorable composition where GFA is likely to be good.^[13] The TM is introduced into the Al–RE binary by increasing the TM content along the composition line such that the desired Al : RE ratio is maintained; the same is done for the RE addition introduced into the Al–TM. The composition at the intersection, where the desirable atomic composition ratios are satisfied and all Al solvent atoms are shared by both the TM and RE solutes, is thought to possess efficient atomic packing, suggesting an energetically stable amorphous state and easy glass formation.

In the following, we describe use of a cluster packing and cluster line model to design the best glass-forming compositions and to tune the GFA in the Al–TM–RE systems. Expanding from an earlier brief report,^[13] we present the results for a number of ternary systems. The effects of additional alloying elements in quaternary and quinary systems on the GFA and thermal stability of the glasses are also evaluated, giving new compositions of fully glassy rods of 1 mm in diameter. We also characterize the glass transition temperature and discuss glass formation with respect to existing models and criteria.

EXPERIMENTAL

Elemental pieces with purity better than 99.9% (99% for Y and La) were used as starting materials. Master alloy ingots with the nominal composition (in at%) were prepared by arc melting under a Ti-gettered argon atmosphere in a water-cooled copper crucible. The alloy ingots were melted six times to ensure compositional homogeneity. For rapidly solidified ribbons, samples were prepared with a cross-section of $0.03\text{--}0.26 \times 3 \text{ mm}^2$ using a single roller melt-spinning technique in an argon atmosphere. Wedge-shaped samples were prepared by casting molten alloys into a wedge-shaped mold with an included angle of 5° . Rod-shaped samples were cast by the injection of the molten alloy into the cavity of a copper mold with a diameter of 1 mm and length of 20 mm.

The axial cross-section surfaces of the as-cast rods were investigated by X-ray diffraction (XRD) using a Rigaku D/max 2400 diffractometer (Tokyo, Japan) with monochromated $\text{CuK}\alpha$ radiation ($\lambda = 0.1542 \text{ nm}$). The glass transition and crystallization of the alloys were analyzed using differential scanning calorimetry (DSC) in a Perkin-Elmer DSC7 calorimeter under flowing purified argon at a heating rate of 20 K min^{-1} . Temperature-modulated differential scanning calorimetry (TMDSC) experiments, used to reveal the glass transition hidden by crystallization in conventional DSC scans, were carried out on a TA Q-100MDSC. TMDSC was carried out at a ramp of 2°C min^{-1} , and modulated temperature of $\pm 0.5^\circ\text{C}$ every 30 s. For most marginal Al-based metallic glasses, the glass transition signal is not obvious in normal DSC curves. Therefore, in our study, we adopted the TMDSC method, a thermal analysis technique developed in the early 1990s, in which a sinusoidal temperature modulation is superimposed on the constant heating or cooling rate of a conventional DSC measurement.^[25,26] The advantage of TMDSC is that the cyclic heating and cooling are very fast and the amplitude is very small, and the reversible and irreversible signals can be obtained during one continuous heating. It is, therefore, a useful tool to reveal hidden reversible processes (e.g. glass transition) even when they overlap with non-reversible processes (e.g. crystallization). The total DSC signal could be deconvoluted into reversible heat flow (Rev. HF) and non-reversible heat flow (Non-rev. HF). The use of TMDSC enables primary crystallization exotherms to be separated from the glass transition itself so that a hidden T_g could be detected. The melting behavior of the alloys was studied using a Netzsch DSC 404C at a heating rate of 20 K min^{-1} . The axial cross-section of the as-cast rods was examined by optical microscope and a LEO (Oberkochen, Germany) Supra 35 scanning electron microscope (SEM) with energy dispersive X-ray analysis. Samples for conventional and high-resolution transmission electron microscopy (TEM) observations in a FEI Tecnai F30 electron microscope were thinned electrolytically by jet polishing in a mixed 1/4 nitric and 3/4 methanol solution at 243 K.

RESULTS

Glass formation in ternary Al–TM–RE systems

We will present the data for several ternary systems to demonstrate our method. In particular, we will select the Al–Ni–Y system for a focused study and as the basis for multi-component higher-order systems. From a structural perspective, it is known from Table 1 that, for the Al–Ni and Al–Y binaries, $\text{Al}_{9,4}\text{Ni}$ (in atomic ratio) and $\text{Al}_{16,9}\text{Y}$ clusters are preferred, respectively.^[15] Our principle is to keep these independent preferable ratios (marked by the stable cluster line) unchanged.

Table 1 Summary of the structural parameters of Al-based amorphous alloys. R_B denotes the atomic radii of B atoms, R_{Al-B} represents the bond distance of Al-B pairs, and N_c is the coordination number

Pair Al-B	R_B	R_{Al-B}	N_c
Al-Al	0.14317	2.74	12.7
Al-Fe	0.12412	2.42	9.5
Al-Co	0.12510	2.41	9.4
Al-Ni	0.12459	2.44	9.4
Al-Y	0.18105	3.18	16.9
Al-La	0.18790	3.34	17.5
Al-Ce	0.18247	3.25	17.0
Al-Gd	0.18013	3.16	16.8

Here, we make a simplification to treat the cluster packing above as equivalent to the following scenario. All the Al atoms are assumed to be in the shell of the clusters, surrounding Y and at the same time also Ni. In other words, each and every Al atom is touching Y and simultaneously Ni. For example, an Al can have Y on the left and Ni on the right, as the Al is shared by the Y- and the Ni-centered clusters. On average, we assume that, in the alloy, the number of Al atoms is such that each Y is seeing 16.9 Al atoms, and each Ni is touching 9.4 Al neighbors (hence the cluster lines in Fig. 1). This way, all the Y (and Ni) neighborhood is at the desired Al : Y (or Al : Ni) ratio, although we have not specified the details as to exactly how the clusters are sharing with one another to achieve this. Based on such a cluster packing and cluster line model, at the composition $Al_{85.8}Ni_{9.1}Y_{5.1}$, both of the desirable atomic composition ratios (Al : Y = 16.9 and Al : Ni = 9.4) are satisfied. So the composition $Al_{85.8}Ni_{9.1}Y_{5.1}$ is projected to have the best GFA. Similarly, the compositions of

$Al_{85.9}Ni_{9.1}La_5$, $Al_{85.7}Ni_{9.1}Gd_{5.2}$, $Al_{85.8}Co_{9.1}Y_{5.1}$, $Al_{85.8}Ni_{9.1}Ce_{5.1}$ and $Al_{85.5}Fe_9Ce_{5.5}$ can be predicted as the best GFA alloys in the ternary systems with other different TM and RE elements. Figure 2 shows the phase diagrams, where the predicted and experimentally located best GFA compositions in these ternary systems are presented. These predicted compositions are away from the locations of the easily forming primary phases and are consistent with the experimentally determined glass forming ranges.^[2,6,7,9,27]

Figure 3 presents the dependence of the GFA on the components and the critical thickness of glass formation. For different TM elements, the Al-Fe-RE system exhibits the minimum critical thickness. However, the critical thickness can be increased with Co and Ni substitution for Fe. Compared with other RE elements, the Al-Ni-Y system gives the best GFA and the largest critical thickness. Figure 4 shows the XRD patterns of all the glassy ribbons at their corresponding critical thickness. They exhibit a broad halo of the amorphous phase without any distinct diffraction peak from crystals. Upon heating, these samples show three distinct exothermic peaks (Fig. 5). The first peak corresponds to nano-Al precipitation, and the following two peaks are attributed to the grain growth of the Al nanocrystals and the formation of some intermetallics, respectively. Not that no obvious glass transition endotherms can be observed in these DSC traces.

For most of the Al-based metallic glasses, it is not easy to distinguish a glass transition signal from the DSC curves, directly or indirectly, since the supercooled liquid region is small such that the glass transition signals are always partially, even completely, overlapping with crystallization signals. The characteristic thermal properties of these glassy alloys are summarized in Table 2. To develop the best GFA alloys in the Al-Ni-Y system, a systematic survey of the compositions around the predicted

Al_{85.8}Ni_{9.1}Y_{5.1} has been made, as shown in Fig. 6. The best glass former is determined to be Al₈₆Ni₈Y₆, very close to the predicted composition. The critical thickness of the fully amorphous ribbon of this alloy is 260 μm, while those for the surrounding compositions are no more than 100 μm. The XRD and DSC results of the Al₈₆Ni₈Y₆, confirm its amorphous nature (Fig. 7).

Glass formation in quaternary system

It is well known that multi-component alloying is beneficial in improving GFA.^[2,28,29] An appropriate atomic size distribution in an alloy system tends to facilitate the dense packing structure of the undercooled liquids and lower their Gibbs energy, resulting in stabilized undercooled liquids and enhanced GFA. We, thus, attempted to introduce additional solutes in partial substitution for Ni or Y, to search for possible BMG formation in Al-rich quaternary systems. The principle of

Table 2 Thermal properties of typical Al-based glass-forming alloys. T_g and T_x are the glass transition temperature and onset crystallization temperature, respectively. T_m and T_l denote the melting temperature and liquidus temperature, respectively. ΔH is the enthalpy release during the devitrification reactions. $\Delta T = T_x - T_g$, $T_{rg} = T_g/T_l$, $\gamma = T_x/(T_g + T_l)$

Alloy	T_g (K)	T_x (K)	T_m (K)	T_l (K)	ΔT_x (K)	T_{rg} (T_g/T_l)	γ	ΔH (J/g)

Al ₈₆ Y _{4.5} Ni ₆ Co ₂ La _{1.5}	505	513	900	1197	8	0.42	0.30	-143

Fig. 6 Compositional triangle for glass formation (critical ribbons thickness) in the Al–Ni–Y system

Fig. 7 DSC curve of the $\text{Al}_{86}\text{Ni}_8\text{Y}_6$ ribbons; inset XRD pattern indicates their amorphous nature

substitution in this study is that the composition ratio in the quaternary systems does not deviate much from the predicted composition ($\text{Al}_{86}\text{TM}_8\text{RE}_6$) to stay close to the best glass-forming composition in the ternary system. For TM solutes, Al–Co and Al–Ni clusters have similar atomic packing configurations and the coordination number of Ni and Co are both 9.4 in the two types of solute-centered clusters (as seen in Table 1). Therefore, Co is added to partially substitute for Ni in the $\text{Al}_{86}\text{Ni}_8\text{Y}_6$ base alloy, with the composition ratio of Al:(Ni,Co):Y fixed. Similarly, La is used to substitute for Y. In experimental tests, we have obtained fully amorphous samples with different critical

Fig. 8 Optical micrograph of alloy $\text{Al}_{86}\text{Ni}_8\text{Y}_{5.5}\text{La}_{0.5}$ under wedge casting, showing amorphous and crystalline regions

thicknesses by wedge casting. Figure 8 displays an optical micrograph of a sectioned and polished $\text{Al}_{86}\text{Ni}_8\text{Y}_{5.5}\text{La}_{0.5}$ sample. Clearly, two distinct regions, with the fully amorphous and crystalline structures, respectively, are observed in the wedge-casting sample.

Figure 9 presents the changes of the critical thickness as a function of Co and La content. When Co content increases from 0.5 to 2 at%, the critical thickness reaches its maximum value of 850 μm at the composition $\text{Al}_{86}\text{Ni}_6\text{Co}_2\text{Y}_6$ and subsequently decreases with further addition of Co (Fig. 9a). Similarly, the critical thickness of the composition $\text{Al}_{86}\text{Ni}_8\text{Y}_{4.5}\text{La}_{1.5}$ is determined to be about 785 μm (Fig. 9b). This reflects that there exists an optimum Co substitution, and for the La as well. The DSC curves of the two optimum compositions are shown in Fig. 10 and the insets are the corresponding XRD patterns. Apparently, the crystallization behavior in these quaternary systems is similar to that in the ternary system. The corresponding characteristic properties are listed in Table 2.

Glass formation in the quinary Al–(Co,Ni)–(Y,La) system

Considering the effectiveness of additional alloying in improving the GFA, we continued to introduce additional alloying elements to explore Al-rich BMGs in quinary systems. The composition ratio of Al:TM:RE of all the BMG-forming alloys remained the same as the ternary alloy composition, $\text{Al}_{86}\text{Ni}_8\text{Y}_6$. By simultaneously

tuning the substituting solutes of La and Co, for Y and Ni, respectively, several fully glassy rods with 1 mm diameter have been successfully obtained at compositions of $\text{Al}_{86}\text{Ni}_6\text{Y}_{4.5}\text{Co}_2\text{La}_{1.5}$, $\text{Al}_{86}\text{Ni}_7\text{Y}_5\text{Co}_1\text{La}_1$ and $\text{Al}_{86}\text{Ni}_7\text{Y}_{4.5}\text{Co}_1\text{La}_{1.5}$ by injecting the molten alloy into

Fig. 13 XRD patterns of rods with 1 mm diameter for several Al-rich bulk amorphous alloys

Fig. 14 DSC curves of Al-Ni-Y-Co-La bulk amorphous samples with a heating rate of 20 K min⁻¹, in which no clear glass transition signals are visible

machined copper molds. Figure 11 shows the outer appearance of the bulk $\text{Al}_{86}\text{Ni}_7\text{Y}_5\text{Co}_1\text{La}_1$ amorphous sample. Furthermore, we present the bulk glass formation range in the quinary system as shown in Fig. 12. The bulk glass formation is strongly composition-dependent. The XRD patterns of the 1-mm rods exhibit no discernible crystallites for the three Al-rich BMGs, while there exist α -Al primary phases in the partial amorphous $\text{Al}_{86}\text{Ni}_6\text{Y}_5\text{Co}_2\text{La}_1$ sample (as in Fig. 13). Figure 14 shows the DSC curves of these bulk amorphous samples. Note that there is no apparent difference among them in the crystallization behavior, reflecting that their internal amorphous structure characteristics are very similar.

Clearly, no crystalline phase can be observed in the SEM images of the as-cast 1-mm rods. To further illustrate their amorphous nature, the high-resolution TEM image and the inset SAED pattern for alloy $\text{Al}_{86}\text{Ni}_7\text{Y}_{4.5}\text{Co}_1\text{La}_{1.5}$ are presented (see Fig. 15). The sample was taken from the center of the 1-mm as-cast rod. No crystals are visible in the high-resolution TEM micrograph and the glass appears to be very uniform at a nanometer scale. The broad halo in the SAED pattern indicates the presence of a monolithic amorphous phase, which agrees well with the XRD result that the sample is fully amorphous.

DISCUSSION

Model predictions for the ternary Al–TM–RE systems

Although the metallic glass structure is random in the long range, the local structure is relatively organized at the sub-nanometer scale. For Al-rich glasses, solute-centered quasi-equivalent clusters can be viewed as the basic local motifs. The relative atomic sizes of the solvent and solute species and the nature of the chemical interactions of the atoms determine the clusters' geometry and stability, and consequently their ability to avoid devitrification. As mentioned earlier, Miracle and co-workers^[22,23,30] proposed an efficient cluster-packing (ECP) model to depict the atomic structure of metallic glasses. In this model, the local cluster is composed of a single solute atom surrounded entirely by solvent atoms, where atoms are modeled as hard spheres. When the cluster is efficiently packed, as all the surrounding solvent atoms touch each other and the center solute, the local volume and the energy of the system are minimized. Miracle's scheme assumes face-centered cubic (fcc) dense packing of "α clusters" in the ECP model. Following this model, assuming that the α sites are fully occupied by Y in the Al–Ni–Y system, while the β and γ sites are occupied by Ni, the possible glass-forming compositions in the Al–Ni–Y system are predicted (Table 3). It can be seen that, when β sites are completely filled with Ni and γ sites are vacant, the glass-forming composition predicted in the Al–Ni–Y system is $\text{Al}_{83}\text{Ni}_{8.5}\text{Y}_{8.5}$. This is close to, but not exactly on, the experimentally determined composition favorable for glass formation, i.e. $\text{Al}_{86}\text{TM}_8\text{RE}_6$.

Based on the chemical effects on atomic packing and the strain produced by β solute filling, a modified ECP (MECP) model was recently developed by Wang et al.^[31] Following this model, the atom that has larger bonding energy or negative heat of mixing with the solvent is designated as the primary cluster-forming solute α, and the other atoms are regarded as β. Thus, the glass-forming compositions predicted in the Al–Ni–Y systems are $\text{Al}_{62.2}\text{Ni}_{31.2}\text{Y}_{6.6}$ (Table 3). The calculated result is far

Table 3 Comparisons of the best GFA compositions predicted by different models in the Al–Ni–Y system

Alloy system	Al–Ni–Y
ECP model	
β filled with Ni atom, γ vacant	$\text{Al}_{83}\text{Ni}_{8.5}\text{Y}_{8.5}$
β filled with Ni atom, γ half filled with Ni atom	$\text{Al}_{76.9}\text{Ni}_{15.4}\text{Y}_{7.7}$
β filled with Ni atom, γ filled with Ni atom	$\text{Al}_{71}\text{Ni}_{21.7}\text{Y}_{7.3}$
MECP model	$\text{Al}_{62.2}\text{Ni}_{31.2}\text{Y}_{6.6}$
Modified by λ criterion	$\text{Al}_{81}\text{Ni}_{12.4}\text{Y}_{6.6}$
Cluster line model	$\text{Al}_{86}\text{Ni}_9\text{Y}_5$
Experimental composition	$\text{Al}_{86}\text{Ni}_8\text{Y}_6$

from the experimentally determined favorable composition, although the Y content is close to the ECP model prediction.

One could also use the λ criterion, based on the original idea of Egami,^[32] to modify this composition, as seen in Table 3. However, Ni content is still higher than the experimental value, while the model-predicted Y content is reasonable. We conclude that these models do not adequately predict and explain the BMGs in Al-based systems.

The predicted best glass-forming alloy following our cluster line approach, as shown in Fig. 1, is $\text{Al}_{86}\text{Ni}_9\text{Y}_5$, which is the closest when compared with the experimentally identified best composition for the ternary Al–TM–RE system, as shown in Table 3. The inter-cluster packing in this case^[15] is characterized by a dense, random connection of quasi-equivalent clusters, with a tendency for icosahedral-like arrangement.

Applicability of the GFA criteria for Al-based metallic glasses

The GFA of Al-based metallic glasses is obviously much lower than that of many other BMGs.^[33] It has been known for many years that, unlike the BMGs based on Zr, Pd and RE with high GFA, the Al-based amorphous alloys do not generally form at eutectics, which are compositionally located very close to the Al-rich corners.^[2] Al crystals often come out easily as the primary phase, limiting the formation of Al-based metallic glass.

Some characteristic temperatures based on thermodynamic parameters are used for evaluating the GFA, e.g. the supercooled liquid region ΔT_x ($\Delta T_x = T_x - T_g$, where T_x is the onset crystallization temperature, T_g is the glass transition temperature) and T_{rg} is $(T_{rg} = T_g/T_l)$ glass transition temperature T_g over liquidus temperature T_l .^[34] Generally, the amorphous structure will be easily formed by increasing the values of T_{rg} , and a larger ΔT_x is beneficial to obtain higher GFA alloys. Recently, Lu and Liu^[35] developed another parameter, $\gamma (= T_x/(T_g + T_l))$ to evaluate GFA. The value of γ is claimed to be associated with the critical cooling rate of the supercooled liquid and the critical thickness

Fig. 16 Typical TMDSC results for $\text{Al}_{86}\text{Ni}_6\text{Y}_{4.5}\text{Co}_2\text{La}_{1.5}$ glassy rod at a heating rate of 2 Kmin^{-1} which illustrates the total heat flow, reversible heat flow (Rev. HF) and non-reversible heat flow (Non-rev. HF). A glass transition signal is clearly observed

of the sample. For most BMGs, the γ value is in the range 0.35–0.5, while ΔT_x ranges from 16 to 117 K and T_{rg} varies from 0.5 to 0.69.

Figure 16 shows the TMDSC results for $\text{Al}_{86}\text{Ni}_6\text{Y}_{4.5}\text{Co}_2\text{La}_{1.5}$ metallic glass obtained at an underlying heating rate of 2 Kmin^{-1} . The three curves represent reversible, non-reversible and total heat flow, respectively. The T_g of the $\text{Al}_{86}\text{Ni}_6\text{Y}_{4.5}\text{Co}_2\text{La}_{1.5}$ determined in Fig. 16 is 505 K. The T_g of the other bulk glass samples along with other data including T_x , T_m , T_i , T_{rg} , ΔT_x and ΔH are listed in Table 2. Note that the ΔT_x of the BMG samples is in the range 6–15 K, and the values of T_{rg} are very low at ~ 0.42 . Thus, these thermodynamic parameters indicate a marginal glass former. In addition, Table 2 lists another important quantity, ΔH , the enthalpy release of the sample. The ΔH values of the BMG samples have smaller magnitude than that of the $\text{Al}_{86}\text{Ni}_8\text{Y}_6$ sample with a lower GFA. This suggests that the BMGs are relatively more stable (closer in enthalpy to the crystallized state).

Effect of chemical interaction on GFA in Al-based metallic glasses

Chemical interactions between elements affect the structure of metallic glasses. High levels of attraction between the solvent and solutes encourage the formation of the solvent-solute clusters and improve their stability. Particularly, electronegativity, as a factor representing the atomic bonding, is of importance in understanding the GFA of MGs. Fang et al.^[36] combined the atomic size parameter and the electronegativity difference to evaluate the GFA in Mg-based MGs. It demonstrated that there is a linear relationship between the parameters and thermal stability of the Mg-based BMGs. Inoue et al.^[37] found that the supercooled liquid region in the Al–RE–Ni–Co alloys increased linearly with increasing electronegativity of the RE element within a certain composition range. We found that electronegativity, similar to atomic size distribution,

exhibits a concave downward shape for Al-based metallic glasses and, for Al–Ni–RE systems, there is a critical electronegativity difference, which can distinguish the crystallization types.^[38] Therefore, the chemical bonding is a crucial factor that affects metallic glass formation. Based on Hume-Rothery rules, the atomic electronegativity difference can reflect the bonding nature and even the magnitude of the mixing heat in alloys. Elements with similar electronegativity tend to form solid solutions. With an increase in electronegativity difference between constituent elements, the formation of certain clusters is favored. However, if the electronegativity difference between constituent elements is too large, equilibrium compounds will be formed. Based on chemical considerations, there should be an appropriate value of electronegativity for glass formation, and Eq. 1 can be used for evaluation:

$$\Delta E = \sum_{i=1}^n C_i \times E_i \quad (1)$$

where ΔE represents the average electronegativity, E_i and C_i are the electronegativity and atomic concentration of each element, respectively. Figure 17 shows the relationship of the critical amorphous thickness and corresponding average electronegativity values of the Al–TM–RE systems. The critical thickness of all the Al-based metallic glasses studied reaches the maximum when $\Delta E = E_{\text{Al}}$ (1.61). Thus, the best glass-forming composition appears to correlate with the point where the average electronegativity value of the system is 1.61 (which may reflect a mixture of metallic and covalent bonding in the Al glasses).^[8] The experimental data indicate that the GFA decreases when the average electronegativity deviates from the optimum values of 1.61.

This electronegativity approach allows for the design of Al-rich metallic glasses to be more efficient. For the Al–Ni–Y system, a composition $\text{Al}_{85.8}\text{Ni}_{9.1}\text{Y}_{5.1}$ is predicted by our cluster packing model. We can modify this composition by the average electronegativity restriction

Fig. 17 Relationship between average electronegativity and glass-forming critical thickness in the Al–TM–RE system

(optimization at 1.61). The modified composition $\text{Al}_{86}\text{Ni}_8\text{Y}_6$ exactly corresponds to the best glass former in the ternary system.

CONCLUSIONS

An approach for designing and predicting the best glass-forming composition is proposed for Al-rich systems, based on an understanding of the internal amorphous structure of the glasses. Detailed search results for BMG formers in the ternary and higher-order systems have been presented. Fully glassy rods of 1 mm in diameter have been successfully obtained at compositions of $\text{Al}_{86}\text{Ni}_6\text{Y}_{4.5}\text{Co}_2\text{La}_{1.5}$, $\text{Al}_{86}\text{Ni}_7\text{Y}_5\text{Co}_1\text{La}_1$ and $\text{Al}_{86}\text{Ni}_{7.45}\text{Y}_{4.5}\text{Co}_1\text{La}_{1.5}$. It was found that the addition of elements with similar atomic sizes (configurations) improved the GFA in Al-rich quaternary and quinary systems. The glass transition temperatures of the BMGs have been measured. Glass formation is discussed with respect to existing criteria and previous parameters/models.

Abstract

The phase composition and microstructure of ternary alloys, Al–Ca–X (where X = (Silicon) Si, (Magnesium) Mg, (Zinc) Zn, (Copper) Cu, (Nickel) Ni, (Iron) Fe, (Manganese) Mn, and (Scandium) Sc), developed based on Ca-containing eutectics have been studied. In most systems, ternary compounds are detected. It is found that the structure of Ca-containing eutectics is much finer than that of Al–Si alloys. Such alloys have a good combination of technological properties during casting and deforming. Because of the high volume fraction of Ca-containing particles (up to 33 vol.%), they may be considered as promising “natural composites.” The strength properties of Al–Ca–X alloys may be significantly enhanced by adding Sc and Zr, forming $L1_2$ nanoparticles. Alloys of the system Al–Zn–Mg–Ca can reach hardnesses higher than 200 HB, which gives reason to expect good strength properties. With the example of the Al–9%Zn–3.5%Mg–3%Ca model experimental alloy based on the (Al) + (Al,Zn)₄Ca eutectic, the possibility, in principle, of manufacturing rolled sheets has been demonstrated.

Keywords: Al–Ca eutectic; Al₃Sc nano-particles; Hardening; Heat treatment; Microstructure; Phase composition.

INTRODUCTION

In the last few decades, the use of aluminum in products used for new technology—automotive, aviation, construction—has significantly increased.^[1–5] The rapid development of technology leads to increased property requirements for aluminum alloys. In the 1960s and 1970s, scientists thought that the potential to improve the properties of aluminum alloys by alloying had been exhausted and therefore developed new technologies to enhance the properties of materials (powder metallurgy,^[6–8] composite materials,^[9–11] granular alloys,^[12–15] and others). The improved mechanical properties in these materials are due to the structure, consisting of a ductile matrix and uniformly distributed reinforcing solid particles. However, these technologies are complicated and expensive, so in the 1990s, some researchers began to study eutectic alloys. In these alloys, the matrix is an aluminum solid solution (henceforth “(Al)”), and the reinforcing component is eutectic intermetallic particles. Thus, eutectic alloys based on the systems Al–Ni,^[16–20] Al–Ce–Ni,^[21,22] and Al–Ce–Cu^[23,24] have been offered. The basic principles of creating such eutectic alloys are formulated in Refs. [25,26]. These alloys should meet the following conditions:

- The eutectic concentration of the alloying element AE1 (eutectic-forming element, particularly Ni and Ce) should provide a volume fraction of intermetallic compound in the range 10–30%.
- Crystals of eutectic intermetallic compounds must be smaller than 1–3 μm . Upon annealing, they should be divided into fragments and rounded for a short time (no more than 3–4 h).
- It is advisable that the AE1 elements have a very low solubility in aluminum.

Then, the AE2 alloying elements (elements for dispersoid formation: (Chromium) Cr, (Titanium) Ti, (Manganese) Mn, and particularly (Scandium) Sc and (Zirconium) Zr) should be added to the alloys.

All these requirements are satisfied by compositions based on the Al–Ca system. Calcium (AE1) is an inexpensive alloying element, and moreover, it is contained in the Earth’s crust in large quantities (3.6%). Calcium occupies third place among all the metals, trailing only aluminum and iron.^[2] The system Al–Ca contains a eutectic (Al) + Al₄Ca^[27,28] with a finer structure than the eutectic (Al) + Si (which is the basis of the most widely used casting alloys of the 4xx/3xx series).^[29]

In recent years, many publications considering calcium-containing magnesium alloys have appeared.^[30–32] At the same time, the use of calcium for the alloying of aluminum alloys is very limited. As a rule, this element is considered to be a harmful impurity. Several attempts to develop alloys based on the Al–Ca system (in particular those with increased zinc content), which were characterized with a tendency to superplasticity, were made at the end of the previous century.^[33–35] There are no literature data covering the possibility of using Ca as an alloying element for casting aluminum alloys, although the structure of the Al–Ca phase diagram (Fig. 1a) gives promising predictions. A limited amount of experimental data can be found in the literature for the Al–Ca–X ternary systems (where X is (Silicon) Si, (Magnesium) Mg, (Zinc) Zn, (Copper) Cu, (Nickel) Ni, (Iron) Fe, and others).^[27,36–39]

Among AE2 additives, scandium provides the most significant hardening effect due to the formation of coherent Al_3Sc (L1_2) phase precipitates with sizes less than 10 nm.^[40–44] These nanoparticles result from decomposition of (Al) during annealing. This specific feature of these alloys enables a significant increase in the strength of aluminum alloys without

the classical T6 hardening heat treatment (solution treatment + quenching + aging). Among these alloys, wrought alloys based on the Al–Mg system^[45,46] are used most widely. Despite its high cost, currently scandium (as a rule together with zirconium) is considered to be one of the most promising alloying elements in new-generation aluminum alloys.^[41] However, in the most famous cast Al–Si alloys, scandium additives do not give the same hardening effect.^[29,40,47] We assume that in the alloys based on the Al–Ca system, scandium additives will be more effective than in the alloys of the 3xx/4xx series.

However, scandium additives (even in combination with other AE2s) do not allow strengths higher than 500 MPa. It is well known that commercial high-strength aluminum alloys (7075, 7055, 7085, etc.) belong to the Al–Zn–Mg–Cu system, where the summed content of zinc, magnesium, and copper constitutes 12–13 wt.% (Zn + Mg up to 10 wt.%).^[48–55] However, because of the small amounts of the eutectic, alloys of the 7xxx type have very low casting properties (in particular hot tearing). For this reason, the usage of these alloys for the production of complicated castings is difficult, although several attempts were made.^[16] Calcium eutectics can be added to

Fig. 1 The Al–Ca phase diagram (a) and microstructure of as-cast Al–7.6%Ca eutectic alloy, OM (b,d), SEM (c); (b,c) as-cast, (d) annealed at 600°C, 3 h

improve the casting properties of 7xxx-type alloys. The phase diagram of the quaternary Al–Ca–Mg–Zn system is unknown. Some initial information about the alloys of this system, presented in Refs. [56,57], shows the possibility of developing high-strength alloys based on the aluminum–calcium eutectic.

Based on the earlier information and taking into consideration the scarcity of information regarding aluminum alloys with the addition of calcium, the following main objectives of this work have been formulated:

1. to study the phase composition and microstructure of alloys of the Al–Ca–X systems (where X = (Silicon) Si, (Magnesium) Mg, (Zinc) Zn, (Nickel) Ni, (Iron) Fe, (Manganese) Mn, and particularly (Scandium) Sc) in the as-cast and heat-treated states.
2. to study the hardening effect in Al–Ca–X–Sc(Zr) alloys, reached without quenching, due to the formation of coherent $L1_2$ -phase precipitates.
3. to study the structure, phase composition, and strength potential of eutectic alloys based on the Al–Zn–Mg–Ca system.

The purpose of this study is to demonstrate the possibility of adding calcium for developing eutectic aluminum alloys of a new generation (both casting and wrought) of composite type.

Al–Ca AND Al–Ca–X PHASE DIAGRAMS

Al–Ca System

The Al–Ca phase diagram is the eutectic type in Al-rich field. According to the data in Refs. [27–29], in the Al–Ca system the $L \rightarrow (Al) + Al_4Ca$ eutectic reaction takes place at 7.6% Ca and 617°C, which is rather close to the calculated values obtained by the Thermo-Calc software application (Fig. 1a). The compound Al_4Ca has a body-centered tetragonal lattice (10 atoms per cell), space group I4/mmm (parameters $a = 0.436$ nm, $c = 1.109$ nm), density 2.35 g/cm³, and hardness 200 HB.^[27]

The calcium-containing eutectic has a finer morphology than the aluminum–silicon eutectic.^[29] Moreover, optical microscopy cannot resolve the internal structure of the former eutectic as the eutectic dendrites have submicron sizes (Fig. 1b). As Fig. 1c shows, the average thickness of eutectic dendritic branches is about 0.5 μ m.

It is known that the fineness of the eutectic structure in the as-cast state determines, to a great extent, its capability to change its form during heat treatment.^[16] A study on the influence of the annealing temperature (with 3-h holding) on the morphology of the eutectic constituents detected the first symptoms of fragmentation at 450°C.^[29] With the increase in the temperature, the changes became detectable at the resolution of

optical microscopy. At 500°C, almost all Al_4Ca particles took a globular form, but their sizes remained submicron. At the maximum tested temperature of annealing (600°C), the structure became much coarser: the size of some particles reached 5 μ m (Fig. 1d). It should also be noted that the volume fraction of Al_4Ca particles in the eutectic alloy is about 33 vol.%, which is much higher than the amount of silicon particles in Al–Si eutectic alloys (about 11 vol.%). This makes it possible to increase considerably the properties that are controlled by the mixture rule (e.g., thermal expansion coefficient, modulus of elasticity).

Al–Ca–Si System

According to the known data,^[27] this system contains the compound Al_2Si_2Ca , which is involved in three eutectic reactions. Among these eutectics, the ternary eutectic (Al) + Al_4Ca + Al_2Si_2Ca (612°C, 7–8% Ca and 0.8–1.1% Si) can have a finer structure than the binary eutectic (Al) + Al_4Ca . We believe that the alloys based on this ternary eutectic may have a good combination of various processing and mechanical properties. It should also be taken into account that in the alloys based on the Al–Si system, calcium is considered as a harmful impurity due to the features of the phase diagram of Al–Ca–Si near the binary system Al–Si.^[27]

This ternary system has been studied recently by the authors of the present article.^[58] The concentrations of (Calcium) Ca and (Silicon) Si in the experimental alloys were chosen based on the results of Al–Ca–Si phase diagram calculations. The main feature of this ternary system is a vast area of primary crystallization of the Al_2Si_2Ca compound (Fig. 2a). As shown in the vertical section that was calculated at 94% Al (Fig. 2b), a small addition of calcium (less than 0.1%) in binary Al–Si alloys dramatically increases the liquidus temperature (T_L). From Fig. 2b, it also follows that the addition of Si up to 0.8% in the Al–Ca alloys should not increase T_L . At contents of silicon up to 0.5%, the Al_2Si_2Ca compound can be formed only via the eutectic reaction: $L \rightarrow (Al) + Al_4Ca + Al_2Si_2Ca$.

The microstructure of the hyper-eutectic alloys, as predicted by thermodynamic calculations (Fig. 2), contains the primary crystals of the Al_2Si_2Ca compound, which have the form of polyhedrons (Fig. 3a). According to the elemental mapping data obtained by electron microprobe analysis (EMPA), these crystals are enriched by silicon and calcium (Fig. 3b–d). According to the quantitative analysis, the composition of primary crystals in all studied alloys is close to the Al_2Si_2Ca compound formula (Table 1).

According to Fig. 4a, the ternary eutectic has a highly fine structure (the size of the dendritic branches is less than 0.2 microns). The experimentally determined concentrations of calcium and silicon in the eutectic are close to the

Fig. 3 Primary crystals of $\text{Al}_2\text{Si}_2\text{Ca}$ phase in as-cast alloy Al–4%Ca–4%Si (a) SEM image; (b–d) EMPA elemental mapping: (b) Al, (c) Ca, and (d) Si

Table 1 Average composition of $\text{Al}_2\text{Si}_2\text{Ca}$ primary crystals in Al–Ca–Si alloys

Alloy (wt.%)	Concentration, wt.% (at.%)		
	Al	Si	Ca
Al–4%Ca–14%Si	36.6 (40.9)	36.1 (38.7)	27.1 (20.3)
Al–4%Ca–4%Si	36.6 (40.8)	36.6 (39.1)	26.6 (20.0)
Al–10%Ca–4%Si	36.5 (40.7)	36.4 (38.9)	27.0 (20.3)

calculation results (point E in Fig. 2a). The study on the influence of the annealing temperature (with 3-h holding) on the morphology of the eutectic constituents detected the first symptoms of fragmentation at 450°C. At 500°C, almost all Al_4Ca and $\text{Al}_2\text{Si}_2\text{Ca}$ particles took a globular form, but their sizes remained submicron (Fig. 4b). At the maximum tested temperature of annealing (550°C), the structure became much coarser, and the size of some particles reached 5 μm (Fig. 4c).

Fig. 4 Morphology of eutectic (Al)+(Al₄Ca)+Al₂Si₂Ca in alloy Al–6%Ca–0.6%Si–0.3%Sc, SEM: (a) as-cast, (b) annealed at 500 °C, 3 h, (c) annealed at 550 °C, 3 h

We suggest creating new casting aluminum alloys such as “natural composite materials” based on the ternary eutectic (Al) + Al₄Ca + Al₂Si₂Ca.

Al–Ca–Mg System

According to the data in Ref. [36], ternary compounds cannot be in equilibrium with (Al) in the Al–Ca–Mg system. Figure 5a presents a scanning electron microscopy (SEM) image of the alloy Al–10%Mg–4%Ca. It can be seen that this alloy has a hypoeutectic structure and that the Ca-containing eutectic itself is characterized by a moderate dispersity. Veins of the Al₃Mg₃ phase with an enhanced (Magnesium) Mg content are also reliably identified. The concentration of (Magnesium) Mg in (Al) is half as much as that in this alloy. The (Calcium) Ca concentration in (Al) does not exceed 0.01 wt.%.^[59]

We suggest, based on the Al–Ca–Mg system, that casting aluminum alloys with low density, high corrosion resistance, and sufficient strength (not less than for commercial casting alloys of type 520) can be obtained.

Al–Ca–Zn System

A limited amount of experimental data can be found in the literature for the Al–Ca–Zn ternary system.^[36,38,39] In particular, there are conflicting data about compounds containing (Calcium) Ca and (Zinc) Zn. An increase of the

zinc concentration leads to the formation of the primary Ca-containing crystals at lower concentrations of (Calcium) Ca. In particular, they are clearly identified in the Al–10%Zn–6%Ca alloy. According to EMPA, these crystals contain not only calcium but also zinc. The structure of the near-eutectic alloys was mostly eutectic, with a fine morphology of those containing (Calcium) Ca. As an example, the structure of the Al–10%Zn–4%Ca alloy is shown in Fig. 5b. It consists of primary crystals of the aluminum solid solution and eutectic colonies (Al) + (Al,Zn)₄Ca. The joint influence of calcium and zinc on the structure and phase composition of aluminum alloys is discussed in more detail “High-Strength Alloys Based on Al–Ca–Zn–Mg System” section.

Al–Ca–Cu System

According to the available data, in this ternary system two ternary compounds can be in equilibrium with (Al): Al₄CaCu and Al₈CaCu.^[27] We studied two alloys: Al–4%Ca–5%Cu and Al–10%Ca–10%Cu. In the first alloy, there is a relatively fine eutectic. The second alloy contains the primary crystals, whose composition can be described by the formula Al₇Cu₂Ca. The solubility of copper in the Al₄Ca-phase primary crystals is about 6%. The fragmentation of Ca-containing eutectic phase inclusions after annealing at 500 °C is negligible, which makes it difficult to obtain the desired structure with globular inclusions.

Fig. 5 Morphology of Ca-containing eutectics in as-cast ternary alloys Al-Ca-X, (a-c) metal mold, (d) slow cooling: (a) Al-4%Ca-10%Mg; (b) Al-4%Ca-10%Zn; (c,d) Al-6%Ca-3%Ni

Al-Ca-Ni System

In our opinion, the ternary system Al-Ca-Ni seems to be a prospective casting eutectic aluminum alloy. In accordance with Ref. [27], ternary compounds cannot be in equilibrium with (Al), and the eutectic reaction $L \rightarrow (Al) + Al_4Ca + Al_3Ni$ takes place at 6.7% Ca, 5.7% Ni, and 607°C. In the literature, there are also references stating that this ternary system contains the Al_9CaNi compound, which is involved in the eutectic reaction $L \rightarrow (Al) + Al_4Ca + Al_9CaNi$ at 610°C.^[36] All this information required clarification. Thus, we experimentally studied several ternary

alloys. The (Calcium) Ca and (Nickel) Ni contents in the experimental alloys were selected in consideration of the ternary diagram of Al-Ca-Ni (Fig. 6). It should be mentioned that the calculated concentration of nickel in the ternary eutectic is approximately two times less than the data in Ref. [27].

The alloy Al-6%Ca-3%Ni contains colonies of two eutectics: binary with coarse structure (bright) and ternary eutectic with fine structure (Fig. 5c). In the alloy Al-4%Ca-8%Ni, there are distinctly visible primary crystals whose morphological and chemical composition corresponds to the phase Al_3Ni . In the alloy

Fig. 6 Proposed Al-Ca-Ni phase diagram in aluminum corner: (a) phase fields in solid state; (b) liquidus projection (solid lines – calculated and dashed lines – proposed)

Al–10%Ca–4%Ni, primary crystals of two types are detected, compact ones and acicular ones, which cannot be explained just by the simple structure of the diagram of Al–Ca–Ni. It should be mentioned that all the studied ternary alloys contain colonies of fine eutectics. The composition of the acicular crystals corresponds to the expected phase Al_4Ca . The compact crystals, according to the data in Ref. [36], represent the compound Al_9CaNi (~9 at.% Ca and ~9 at.% Ni). The less fine eutectic composition is close to the binary one (Al) + Al_4Ca , and the finer eutectic most probably corresponds to the ternary one (Al) + Al_4Ca + Al_9NiCa . The finer structure of this eutectic in comparison with the Al–Si eutectic is most clearly detected after slow cooling, as shown in Fig. 5d. The silicon-phase particle size in the eutectic Al–Si alloy under the same conditions of solidification is more than 10 times larger.

Generalization of the theoretical data and experimental results allows us to reveal the phase diagram structure for the system Al–Ca–Ni in the region of the aluminum corner. In particular, the two three-phase areas (Al) + Al_4Ca + Al_9NiCa and (Al) + Al_9NiCa + Al_3Ni (Fig. 6a), which correspond to the variant described in Ref. [36], are revealed. Experimentally defining the composition of the ternary eutectic (Table 2) allows the estimation of the liquidus projection of this ternary system (Fig. 6b). Taking into account the other ternary phase diagrams in the aluminum corner,^[16,27,60] it is conceivable that two non-variant reactions occur: a eutectic one ($\text{L} \rightarrow (\text{Al}) + \text{Al}_4\text{Ca} + \text{Al}_9\text{NiCa}$, point E) and a peritectic one ($\text{L} + \text{Al}_3\text{Ni} \rightarrow (\text{Al}) + \text{Al}_9\text{NiCa}$, point P).

Annealing, starting from 500°C, leads to the eutectic morphology changing: first the fragmentation of the aluminides is observed, then their coarsening. As shown in the alloy Al–6%Ca–3%Ni, after annealing at 600°C, the eutectic excluding (Al) contains two types of particles, light and gray (Fig. 7), which indicates that the eutectic is three phase. The EMPA results confirm the identification of the phases Al_4Ca and Al_9NiCa .

The fluidity of the Al–6%Ca–3%Ni alloy with optimal composition appreciably exceeds the Al–7%Si alloy. The obtained data show the possibility of developing casting aluminum alloys based on the (Al) + Al_4Ca + Al_9NiCa eutectics.

Table 2 Average compositions of constituents in as-cast alloy Al–10%Ca–4%Ni

Structural constituent	Concentration, wt.% (at.%)		
	Al	Ca	Ni
Primary Al_9NiCa	69.5 (88.7)	12.2 (9.5)	18.3 (9.8)
Primary Al_4Ca	72.8 (79.9)	26.9 (19.9)	0.3 (0.2)
Eutectic (Al)+ Al_4Ca + Al_9NiCa	89.5 (93.4)	7.1 (5.0)	3.4 (1.6)
Eutectic (Al)+ Al_4Ca	91.8 (94.5)	7.2 (5.0)	1.0 (0.5)

Fig. 7 Microstructure of ternary eutectic (Al)+ Al_4Ca + Al_9NiCa in alloy Al–6%Ca–3%Ni after annealing at 600°C, 3 h

Al–Ca–Fe System

In accordance with Ref. [36], ternary compounds cannot be in equilibrium with (Al). We experimentally studied two alloys: Al–4%Ca–1%Fe and Al–10%Ca–1%Fe. In both alloys, there is a fine eutectic, probably ternary since it contains iron (about 7% Ca and 1% Fe). In the alloy with 10% Ca, there are primary crystals with a compact morphology. Their chemical composition corresponds to the formula $\text{Al}_{11}\text{Fe}_2\text{Ca}$. A certain fragmentation of the eutectic of the Ca-containing phase after annealing at 500°C is observed.

The presence of the ternary compound suggests a different phase equilibrium of the Al–Ca–Fe system as compared with Ref. [36]. Probably, it will be the same as for the Al–Ca–Ni system (Fig. 6). Based on the Al–Ca–Fe system, it is assumed that casting “natural composites” with increased high-temperature strength can be developed.

Al–Ca–Mn System

Manganese is one of the traditional aluminum alloying agents. As it increases the alloy’s strength and corrosion resistance,^[1,2] it was chosen as an additive for alloys based on the binary eutectic (Al) + Al_4Ca . According to the literature data,^[36] in the ternary system there is a compound Al_9CaMn_3 , which may be in equilibrium with (Al). The presence of this compound makes the Al–Ca–Mn ternary system similar to the Al–Ca–Ni phase diagram (Fig. 6). We experimentally investigated several alloys containing up to 10% Ca and 3% Mn. Eutectics in these alloys exhibit a much finer structure than that of other alloy systems such as Al–Ca–X. The composition Al–7%Ca–1%Mn seems optimal. In this fully eutectic alloy, the primary crystals of intermetallic phases are not found. The alloy Al–4%Ca–3%Mn contains chains of compact crystals, the content of which, by the EMPA data, corresponds to the well-known composite Al_6Mn (these particles contain no calcium). The alloy Al–10%Ca–1%Mn contains two types of crystals: compact and needle-shaped ones. The composition of

these crystals is close to the compounds $\text{Al}_{11}\text{Mn}_2\text{Ca}$ (some source data indicate $\text{Al}_9\text{Mn}_3\text{Ca}$) and Al_4Ca , respectively. The fluidity of the Al–7%Ca–1%Mn alloy, which has the optimum composition, significantly exceeds the Al–7%Si alloy. Preliminary studies of the ductility of these alloys show that they can be used to produce deformed semi-finished products by hot rolling (at 450°C and degree of deformation over 80%). Thus, the Al–Ca–Mn system can be used as a basis for the production of “natural composites” having multipurpose processing properties.

Al–Ca–Sc System

The phase composition and structure of alloys of the Al–Ca–Sc system in the aluminum corner (up to 10% Ca and up to 1% Sc) were studied in Ref. [29]. It was shown that only phases of the binary systems (Al_4Ca and Al_3Sc) may be in equilibrium with the aluminum solid solution (Fig. 8). The solubility of scandium in the Al_4Ca phase and calcium in the Al_3Sc phase is negligible. According to the calculation of the ternary phase diagram, calcium reduces the solubility of scandium in (Al) down to 0.2%. However, under conditions of nonequilibrium solidification, there is a shift of the phase boundaries (see the dotted line in Fig. 8). Therefore, the eutectic alloy Al–7.6%Ca–0.3%Sc (with maximal solubility of Sc in (Al)) was chosen for the basic experimental alloy considered in “Al–Ca and Al–Ca–X Phase Diagrams” section.

EFFECT OF Sc AND Zr ON THE HARDENING OF Al–Ca EUTECTIC ALLOYS

The main object of the study was the Al–7.6%Ca–0.3%Sc alloy. The principal difference between the as-cast structures of this alloy and the reference Al–0.3%Sc alloy is that the size of the dendritic branches of the aluminum solid solution in the (Al) + Al_4Ca eutectic of the Al–7.6%Ca–0.3%Sc alloy is less than 1 μm , like in the binary Al–7.6%Ca alloy (Fig. 1b,c). Therefore, the aluminum

Fig. 8 Phase diagrams Al–Ca–Sc: liquidus lines: bold – calculated (equilibrium), dotted – shift after unequilibrium solidification (experimental)

solid solution dissolution and the formation of Al_3Sc precipitates occur near the (Al)/ Al_4Ca interfaces. To study these processes, the method of target photography was used. First, a foil of the Al–7.6%Ca–0.3%Sc alloy was heated in the chamber of the microscope to 300°C, then to 500°C. Stage heating in increments of 50°C with exposure at each stage for 3 h was used. Photographs were obtained for each stage in both bright and dark fields.

Figure 9 shows the extra diffraction spots, which were identified for all the studied states. These spots correspond to the precipitated phase L_{12} . In the selected area, the diffraction patterns allow us to determine the precipitated phases using the superlattice spots,^[41,42] which are in prohibited positions for the face-centered cubic aluminum matrix. After aging at 300°C, which corresponds to the maximum hardening (Fig. 10), the size of the L_{12} precipitates inside (Al) dendrites is minimal (<5 nm). In contrast, the Sc-containing precipitates at the interface with the Al_4Ca eutectic particles are much larger (Fig. 9a,b). When the temperature is increased up to 350°C, the size of the precipitates inside the (Al) dendrites is also increased. However, these precipitates are smaller than those located near the Al_4Ca particles. Heating at 400°C leads to further coarsening of the L_{12} precipitates, and over time, the difference with the interphase precipitates is practically eliminated (Fig. 9c,d). As the temperature increases, the particles coarsen considerably, which makes it possible to detect them using SEM.

The change in hardness depending on the annealing temperature is the result of two processes: coarsening of Al_3Sc precipitates and fragmentation (further spheroidization and coarsening) of Al_4Ca eutectic dendrites. The initial state of both experimental and reference alloys was as-cast. As was shown in Ref. [29], the heating of the binary Ca-containing alloy at 400°C has no influence on the hardness, which can be explained by the absence of any structural changes. At higher temperatures, softening takes place, which can be explained by the change in the Al_4Ca eutectic morphology (Fig. 1d).

In the alloys Al–7.6%Ca–0.3%Sc^[29] and Al–0.3%Sc,^[40–44] visible hardening appears at 250°C, which is connected with precipitation of Al_3Sc nanoparticles. At 300°C, the hardness reaches the maximum, which can be connected with complete precipitation of scandium nanoparticles from (Al) (Fig. 9a,b). Softening of the Al–Ca–Sc eutectic alloy at higher temperatures of annealing is caused, first, by coarsening of Al_3Sc second-phase precipitates (see Fig. 9c,d), and, second, by the morphology change of the Al_4Ca eutectic particles (Fig. 1d). It should be noted that the nature of hardening in both alloys containing 0.3% Sc is very similar, which allows us to deduce the similar features of the Al_3Sc nanoparticles.

It should be noted that the hardness of the Al–7.6%Ca–0.3%Sc model alloy after annealing at 300°C (about 100 HB) is close to the hardness of commercial 356-type alloys in the T6 state.^[1,2] The estimation of the volume fraction (Q_v) of hardening precipitates in the model and

Fig. 9 The Al_3Sc precipitates in alloy $\text{Al}-7.6\%\text{Ca}-0.3\%\text{Sc}$ after annealing at 300°C (a,b) and at 400°C (d,c), TEM: (a,c) bright field; (b,d) dark field and micro-diffraction

commercial 356 alloys shows close values: 0.74 vol.% Al_3Sc and ~ 0.8 vol.% β'' (MgSi), respectively.^[29] This also explains the close values of hardness of these alloys (after the maximum hardening). However, the Al_3Sc phase is thermally stable up to 300°C – 350°C , while the Mg-containing phase loses reinforcing effects during heating above 200°C , since this temperature corresponds to the stage of overaging.^[1,2] As a result, the hardness of the 356 alloy at this temperature decreases significantly, and at 250°C – 350°C it becomes unacceptably low.^[61–63]

Then, we evaluated the degree of hardening of quaternary alloys $\text{Al}-\text{Ca}-\text{Sc}-\text{X}$ (where X is (Silicon) Si, (Magnesium) Mg, (Zinc) Zn, (Copper) Cu, (Nickel) Ni, (Iron) Fe, (Manganese) Mn) with the same contents of scandium. From the hardening curves, shown in Fig. 10a, it follows that for all investigated alloys, the maximum hardening is achieved at 300 – 350°C . This suggests that the hardening in these alloys is due to the formation of Al_3Sc nanoparticles, as shown in Fig. 9a,b. It should be noted that the scandium concentration in the (Al) primary crystals and the eutectic (particularly (Al) + Al_4Ca + $\text{Al}_2\text{Si}_2\text{Ca}$, see Table 3) is approximately the same and is close to its content in the alloy. The exceptions are the high silicon content alloys, which fall within the phase area (Al) + (Si) + $\text{Al}_2\text{Si}_2\text{Ca}$ (Fig. 2). In these alloys, the hardening is virtually absent. This is connected with the low content of scandium in (Al) (less than 0.1%).

Table 3 Average composition of aluminum solid solution and eutectic in as-cast alloy $\text{Al}-6\%\text{Ca}-0.6\%\text{Si}-0.3\%\text{Sc}$

Structural constituent	Concentration, wt.% (at.%)			
	Al	Si	Ca	Sc
(Al)	99.60 (99.76)	<0.01 (<0.01)	0.10 (0.07)	0.29 (0.17)
(Al)+ Al_4Ca + $\text{Al}_2\text{Si}_2\text{Ca}$	90.95 (93.49)	1.04 (1.03)	7.65 (5.29)	0.31 (0.19)

It is known that a similar precipitation hardening of aluminum alloys can also be achieved by the addition of zirconium in an amount of 0.4–0.6%.^[64] This element, like scandium, also allows the formation of L_{12} -phase nanoparticles (in this case Al_3Zr); however, that requires higher casting temperatures.

To replace the expensive scandium, the influence of annealing temperature on the $\text{Al}-4\%\text{Ca}-0.3\%\text{Sc}$ and $\text{Al}-4\%\text{Ca}-0.4\%\text{Zr}$ alloys' hardness was investigated. From Fig. 10b it can be seen that zirconium shifts the hardening maximum toward higher temperatures (from 300 – 350°C to 450 – 500°C). The high hardening temperature of these alloys also allows the formation of globular particles of the Ca-containing phases (Fig. 2b). In alloys with scandium additions such a combination is fundamentally unrealizable.

Fig. 10 Effect of annealing temperature on hardness of as-cast alloys (a) Al-4%Ca-0.3%Sc-X, (b) Al-4%Ca-Sc,Zr

The joint alloying of these additives is promising, as has been shown in Refs. [64–66]. In such alloys, zirconium partially substitutes for scandium in the Al_3Sc phase, forming the $\text{Al}_3(\text{ScZr})$ phase or composite particles with Al_3Sc cores and Zr-enriched shells.^[65]

HIGH-STRENGTH ALLOYS BASED ON Al-Ca-Zn-Mg SYSTEM

The phase composition, structure, and hardening of alloys in the aluminum corner of the Al-Ca-Zn-Mg system were studied by the authors in the following range: 3.5% Mg

and 2.5% Mg, 0–10% Ca, 0–14% Zn (wt.%). Some results were reported in Refs. [56,57]. It was shown that relatively large amounts of zinc enter the Ca-containing phase, so it can be described as $(\text{Al,Zn})_4\text{Ca}$. An increase of the (Zinc) Zn and (Magnesium) Mg content leads to the formation of Ca-containing primary crystals at lower concentrations of calcium. In particular, faceted primary crystals could be easily observed in the microstructure of the alloy Al-12%Zn-4%Ca-3.5%Mg.^[56]

The primary intermetallic crystals are clearly identified in the alloys containing 10% Ca. The EMPA results confirm the presence of zinc in these primary crystals, as was exemplified by the alloy with 14 wt.% Zn (Fig. 11a–d).

Fig. 11 Primary crystals of $(\text{Al,Zn})_4\text{Ca}$ phase in as-cast alloy Al-10%Ca-2.5%Mg-8%Zn. (a) SEM image; (b–d) EMPA elemental mapping: (b) Al, (c) Ca, (d) Si, and (e) Mg

Fig. 12 Zn and Ca concentrations in primary crystals of (Al,Zn)₄Ca phase (see in Fig. 11) versus Zn concentration in alloy

Table 4 Effect of Zn content on average compositions of primary crystals in as-cast alloys containing 10 wt.% Ca and 2.5 wt.%Mg

Zn in alloy, wt.% (at.%)	Concentration in primary crystals, wt.% (at.%)			
	Al	Zn	Ca	Mg
0 (0.00)	73.3 (80.3)	–	26.7 (19.7)	<0.1 (<0.1)
1 (0.43)	67.4 (76.6)	5.8 (2.7)	26.7 (20.4)	0.2 (0.2)
2 (0.86)	66.2 (76.1)	8.2 (3.9)	25.4 (19.7)	0.3 (0.3)
4 (1.74)	59.8 (72.1)	15.5 (7.7)	24.7 (20.1)	0.1 (0.1)
8 (3.58)	53.8 (68.1)	22.9 (12.0)	23.3 (19.9)	0.1 (0.1)
14 (6.61)	38.6 (55.5)	40.9 (24.4)	20.3 (19.7)	0.1 (0.1)

Magnesium is not detected in these crystals, but a large part of it resides in veins, which probably correspond to the MgZn₂ phase. The results of quantitative analysis of the primary crystals’ chemical composition, shown in Table 4, indicate that with an increase of the zinc content in the alloy, the concentration of this element in the crystals is also increased. This increase is almost linear (Fig. 12). On the other hand, the calcium concentration is virtually constant and is approximately 20 at.% (atomic percent). Consequently, in the Al₄Ca compound, zinc can replace

only aluminum. Thus, the formula of this phase can be represented as (Al,Zn)₄Ca. The XRD results show that in the alloys containing up to 8 wt.% Zn, the lattice parameters of the compound fully correspond to the binary compound Al₄Ca. On the other hand, the addition of 14% Zn significantly changes the lattice parameters that are most relevant to the ternary compound Al₂Zn₂Ca.^[36]

The structure of the near-eutectic alloys was mostly eutectic, with a fine morphology of the Ca-containing phase. As an example, the structure of the Al–9%Zn–4%Ca–3.5%Mg alloy is shown in Fig. 13a. It consists of primary crystals of the aluminum solid solution, which have the morphology of dendrite cells, eutectic colonies (Al) + (Al,Zn)₄Ca, and veins of nonequilibrium eutectic, which mostly consist of Al₂Mg₃Zn₃ (T) or Mg₂Zn (M) phases of the Al–Zn–Mg system.^[16,27] According to the DSC cooling curve, the temperature of this eutectic is 469°C.

The EMPA results for the as-cast alloy Al–9%Zn–3%Ca–3.5%Mg showed that only half of the total (Zinc) Zn remains in aluminum solid solution. On the other hand, the zinc concentration in the eutectic exceeds 11 wt.%, i.e., more than its content in the alloy. Calcium is also concentrated in the eutectic, and its content in (Al) is negligible. The concentration of magnesium in (Al) is less than its concentration in the alloy because it partially resides in the nonequilibrium eutectic.

As is mentioned earlier, eutectic alloys in which the morphology of the intermetallic phases is globular have the best combination of mechanical properties. For this reason, one of the main targets of studying the Ca-containing alloys is to determine the tendency of the (Al,Zn)₄Ca phase to spheroidization as well as the peculiarities of this process during heat treatment. Two-step heating was used for the annealing: 450°C, 3 h + 520°C, 3 h. After the annealing, the alloys were quenched in cold water. Dissolution of the nonequilibrium eutectic was the main process running during the first stage of the annealing, while globular particles of (Al,Zn)₄Ca were formed during the second stage. Thus, the favorable microstructure that forms during the annealing in the alloys with large fractions of eutectic is

Fig. 13 Microstructures of the alloy Al–9%Zn–3%Ca–3.5%Mg, SEM: (a) as-cast; (b) heat treated at 520°C

a result of the spheroidization process that was observed during the experiment (Fig. 13b).

Solution treatment leads to complete dissolution of the (Zinc) Zn- and (Magnesium) Mg-containing particles (T or M phases), and the concentration of magnesium in (Al) becomes close to its concentration in the alloy. On the other hand, the concentration of zinc in (Al) is even slightly decreased. Heat treatment does not affect the composition of the Ca-containing eutectic.

In accordance with the analysis mentioned earlier, the alloys with concentrations of Ca close to the eutectic line have the most favorable microstructures, which consist of a matrix based on an aluminum solid solution of the Al–Zn–Mg system and globular particles of the $(\text{Al}, \text{Zn})_4\text{Ca}$ phase. Hardness tests were carried out on quenched alloys after aging at room temperature for seven days (T4) and after aging at 130°C, 20 h (T6). The conditions of the aging were chosen in accordance with data obtained for the Al–Zn–Mg–Ni system. The level of maximal-obtained hardness for the experimental alloys was higher than 200 HB,^[57] which is similar to the data obtained for the alloys of the 7055 type.^[1,2] The influence of calcium on hardness depends on the concentration of (Zinc) Zn: when the concentration of zinc is 6%, the addition of (Calcium) Ca leads to a decrease of the hardness. However, the hardness does not change when the concentration of (Zinc) Zn is 9–12%.^[57] A high level of hardness was observed in a wide range of concentrations of (Zinc) Zn and (Calcium) Ca, which gives a wide enough field for the optimization of the composition of the alloys.

Among other positive effects, it should be noted that the addition of calcium prevents the formation of T and M phases at grain boundaries of the alloys. This effect is especially important for homogenized ingots. To achieve the most unfavorable conditions, selected alloys were annealed at 520°C and then cooled in the furnace (cooling velocity $\sim 0.1 \text{ K s}^{-1}$). The alloys that were not alloyed with calcium had chains along the grain boundaries. Evidently, this type of structure is not satisfactory for work treatment

(extruding, rolling, forging, etc.), because such chains lead to the formation of microcracks and brittle intergranular fracture. Chains appear in alloys with a small addition of (Calcium) Ca. However, no chains were observed in alloys with concentrations of (Calcium) Ca higher than 2%. The microstructures of these alloys were similar to those in the as-quenched state. Due to such a structure in the alloy Al–9%Zn–4%Ca–3.5%Mg (Fig. 13b), it showed good deformability during hot rolling. The microstructure after deformation (reduced by about 80%) resembles the composite (Fig. 14a). The test results of the rolled samples are presented in Table 4. The samples after rolling have an average strength and sufficiently high ductility (9–13%). Figure 14b shows that the fracture has a dimple character. After the heat treatment (quenching in water after annealing at 500°C for 3 h and subsequent artificial aging at 170°C for 3 h (T6)), the strength of the experimental alloy (with a UTS of about 600 MPa) is not less than the strength of the AA7075-type alloys.^[1,2]

The preliminary evaluation of the Al–10%Zn–3%Mg–3.5%Ca alloy fluidity by the filling length of the U-shaped channel shows the advantage of the new alloy over the Al–9%Si composition. The filling length of the Al–10%Zn–3%Mg–3.5%Ca alloy is 440 mm, while it is 370 mm for Al–9%Si. From this follows the high potential to obtain shaped castings from the calcium-containing alloys.

Due to the fact that calcium has a lower density than aluminum, it was evident that its effect on the density of the alloy was positive. The density of the experimental alloy Al–9%Zn–4%Ca–3.5%Mg was found to be markedly lower (2.68 g/cm^3) than that of the commercial alloy AA7075 (2.80 g/cm^3). It was also noted that during heat treatment, the surface of the alloys containing calcium did not darken. Thus, the properties of the oxide surface of the aluminum alloys are improved.

Due to the results mentioned earlier, it can be seen that the Al–Zn–Mg–Ca system is promising for the development of new eutectic-type high-strength aluminum alloys (both casting and wrought).

CONCLUSION

1. Using experimental (optical microscopy and SEM, X-ray microanalysis, differential thermal analysis, etc.) and computational (Thermo-Calc) methods, the phase composition and microstructure of ternary alloys Al–Ca–X (where X = (Silicon) Si, (Magnesium) Mg, (Zinc) Zn, (Copper) Cu, (Nickel) Ni, (Iron) Fe, (Manganese) Mn, (Scandium) Sc) based on Ca-containing eutectics have been studied. Fragments of the phase diagram in the aluminum corner have been studied. In most systems, the ternary compounds have been detected.
2. It is found that the structure of binary and particularly ternary Ca-containing eutectics is much finer than that in Al–Si alloys. This is due to the fact that the Ca-containing eutectics are capable of fragmentation and spheroidization during relatively short exposure to high-temperature annealing. This increases the ductility and deformability of the alloys despite the high volume fraction of Ca-containing particles (up to 33 vol.%). It is found that alloys based on ternary eutectics can be considered as promising for the development of “natural composites.”
3. In the Al–Ca–Si system, the ternary eutectic (Al) + Al_4Ca + $\text{Al}_2\text{Si}_2\text{Ca}$ (612°C, 7–8% Ca and 0.8–1.1% Si) with a highly fine structure (the size of the dendritic branches is less than 0.2 microns) has been detected. The experimentally determined concentrations of calcium and silicon in the eutectic are 7.18% Ca and 0.49% Si, respectively. The study on the influence of the annealing temperature (with 3-h holding) on the morphology of the eutectic constituents detected the first symptoms of fragmentation at 450°C. At the maximum tested temperature of annealing (550°C), the structure became much coarser, and the size of some particles reached 5 μm . The alloys based on this ternary eutectic may have a good combination of various processing and mechanical properties.
4. In the Al–Ca–Zn system, it is found that an increase in the zinc concentration leads to the formation of the primary Ca-containing crystals at lower concentrations of calcium. According to EMPA, these crystals contain not only calcium but also zinc. The structure of the near-eutectic alloys was mostly eutectic (eutectic colonies (Al) + $(\text{Al,Zn})_4\text{Ca}$), with a fine morphology of the calcium-containing phase.
5. Generalization of the theoretical data and experimental results allowed determining the phase diagram structure for the system Al–Ca–Ni in the region of the aluminum corner. In particular, the two three-phase areas (Al) + Al_4Ca + Al_9NiCa and (Al) + Al_9NiCa + Al_3Ni and two nonvariant reactions, a eutectic one ($\text{L} \rightarrow (\text{Al}) + \text{Al}_4\text{Ca} + \text{Al}_9\text{NiCa}$, point E) and a peritectic one ($\text{L} + \text{Al}_3\text{Ni} \rightarrow (\text{Al}) + \text{Al}_9\text{NiCa}$, point P), are revealed. The ternary (Al) + Al_4Ca + Al_9NiCa

eutectic has a fine structure, what suggests the possibility of developing alloys with high processing and mechanical properties. For instance, the fluidity of the experimental Al–6%Ca–3%Ni alloy based on the (Al) + Al_4Ca + Al_9NiCa eutectic appreciably exceeds the Al–7%Si alloy.

6. Experimental investigations of several alloys based on the Al–Ca–Mn systems and containing up to 10% Ca and up to 3% Mn have revealed that the eutectics in these alloys exhibit a much finer structure than that of other alloy systems such as Al–Ca–X. Preliminary studies of the ductility of these alloys show that they can be used to produce deformed semi-finished products by hot rolling (at 450°C and degree of deformation over 80%). Thus, the Al–Ca–Mn system can be used as a basis for the production of “natural composites” having multipurpose processing properties.
7. The strength properties of alloys Al–Ca–X can be significantly enhanced by adding scandium and zirconium due to the formation of L_{12} nanoparticles during heat treatment of the T5 type (without quenching). The annealing temperature for reaching maximum strength is 300°C–350°C in the case of scandium alloying and about 450°C in the case of zirconium alloying.
8. The phase composition, structure, and hardening of the alloys in the aluminum corner of the Al–Ca–Zn–Mg system have been studied. It was shown that a relatively large amount of zinc enters the Ca-containing phase, whose formula can be described as $(\text{Al,Zn})_4\text{Ca}$. The maximal level of hardness observed in calcium-containing alloys was higher than 200 HB, which gives reason to expect good strength properties. With the example of an Al–9%Zn–3.5%Mg–3%Ca model experimental alloy based on the (Al) + $(\text{Al,Zn})_4\text{Ca}$ eutectic, the possibility, in principle, of manufacturing rolled sheets has been demonstrated.

Abstract

The Hall–Héroult process for the electrolytic reduction of alumina was developed at the end of the 19th century and is still currently the only industrial process for the production of primary aluminum. Today, this process is ranked among the most energy- and CO₂-intensive industrial processes. Direct carbothermic reduction of alumina has been proposed as an alternative process, which can substantially improve the sustainability of primary aluminum production, leading to energy savings of up to 21% and reduction in greenhouse gas emission of up to 52%, while plant capital costs can be reduced up to 50%. However, processes developed so far suffer from low aluminum yields, primarily due to aluminum carbide and oxycarbide formation and aluminum vaporization phenomena. This article presents a thermodynamic study of the Al–C–O system and a review on the alumina carbothermic processes developed so far.

Keywords: Alternative processes; Alumina; Aluminum; ARP; Carbothermic reduction; Hall–Héroult.

INTRODUCTION

Today, all of the primary aluminum production follows the Hall–Héroult process for the electrochemical reduction of alumina in a molten salt (cryolite) bath at 960°C. This process is—by design—the most energy- and CO₂-intensive stage in the primary production of aluminum, which in total has a gross energy requirement of 211 MJ/kg Al and contributes to global warming by releasing 22.4 kg CO_{2-equiv}/kg Al,^[1] while the cost of electricity consumed in the Hall–Héroult process accounts for approximately 30% of the total cost of the primary aluminum production. The overall reaction taking place in the Hall–Héroult process is:

The analysis in the review by Welch^[2] presents aluminum reduction chemistry and illustrates the common features of alternative production processes, regardless of methodology. A common pattern in several of these process options is that alumina is converted to less stable aluminum intermediate compounds (e.g., AlCl₃, Al₂S₃, Al₄C₃, or Al₄O₄C). The formation and decomposition of these intermediates always involve separate reactors and require the

study of relevant heat losses, material transfer systems, and recycling challenges. Problems with reactor life and construction materials remain in these alternative processes as they rely on either material-restricting substances, reactive aluminum slags, or molten salts.

Welch identifies the best process as the one that occurs at low temperature and features the highest productivity per unit volume and the fewest number of processing stages. Table 1 summarizes these main alternative processes for aluminum production. Sustained R&D has been pursued for only two of the five alternative processes presented in the last 25 years (these are the drained cell technology and the inert anode electrolytic cells).

Carbothermic reduction is the only non-electrochemical process for aluminum production that has been proposed and tested, and it has received considerable and sustained attention for decades: corporate R&D interest is strong, and open metallurgical literature publications are abundant. This alternative aluminum production process is based on a homogeneous high-temperature endothermic reduction reaction occurring between aluminum oxide (Al₂O₃) and carbon (C). Theoretically, this is described by the following chemical reaction:

Table 1 Alternative processes for aluminum production^[2]

Production process	Features
Drained-cell technology ^a	Cathode sloping and coated with aluminum-wettable TiB ₂ . By eliminating metal pad, anode-cathode gap could be halved to ~25 mm, enabling substantial voltage lowering. Other basic features remain the same ($E^\circ \sim 1.2$ V, $\Delta_{\text{min,electrolysis}} = 6.34$ kWh/kg).
Inert anode cells ^a (oxygen evolution)	Eliminate consumable carbon anode by having an electrode material that evolves oxygen. Although the electrochemical potential would increase by 1 V ($E^\circ \sim 2.2$ V), the voltage increase would be less because of lower anode polarization ($\Delta_{\text{min,electrolysis}} = 9.26$ kWh/kg). The superstructure of the existing cell could be refined, reducing capital costs. If drained-cell materials development were successful, further design options are possible.
Chloride process ^b	Aluminous material converted to (anhydrous) aluminum chloride (AlCl ₃) of adequate purity. Aluminum chloride electrochemically decomposed in a multi-electrode cell at ~700°C. Electrochemically generated Cl ₂ is recycled ($E^\circ \sim 1.8$ V, ($\Delta_{\text{min,electrolysis}} = 6.34$ kWh/kg).
Sulfide process ^b	Aluminous material converted to anhydrous aluminum sulfide (Al ₂ S ₃) of adequate purity. Aluminum sulfide electrochemically decomposed to recyclable S ₂ and aluminum ($E^\circ \sim 1.0$ V) in a multipolar ($\Delta H_{\text{min,electrolysis}} = 5.24$ kWh/kg) electrochemical cell.
Carbothermic reduction ^b	Convert alumina material to intermediate Al ₄ C ₃ or Al ₄ O ₄ C chemically at $T > 1700^\circ\text{C}$. React Al ₂ O ₃ with Al ₄ C ₃ to evolve CO and produce Al (or alloy) at $T > 2000^\circ\text{C}$. Refine the metal quality to a usable grade ($\Delta H_{\text{minimum}} = 9.0$ kWh/kg).

Notes: ^aSubstantial retrofits using cryolite-alumina electrolytes.

^bProcessing using intermediates derived from alumina.

which according to equilibrium thermodynamic calculation is possible above 2037°C, as at that temperature it has a free Gibbs energy potential of $\Delta G^0 = -549.9$ J (calculation using Factsage 7.0 software^[3]).

Advantages in Carbothermic Reduction

A number of attractive characteristics explain the deep interest in carbothermic aluminum.^[2,4] Assuming such a process happening in an electric arc furnace with at least 90% aluminum yield then, compared to the Hall–Héroult process, the carbothermic reduction of alumina could achieve 32% energy savings (assuming utilization of coal-based electricity for both processes and including the energy of the coal used as reductant in the energy consumption of the carbothermic reduction of alumina) and a reduction of 39% in direct greenhouse gas (GHG) emission (including the elimination of perfluorocarbon (PFC) emissions).^[5] In this scenario, the overall energy utilization efficiency of primary aluminum production would increase as more carbon is directly utilized in the chemical reduction process rather than being burned to produce electricity to power the electrochemical reduction process. Additionally, the hot CO gas produced from the process would be a potential heat and energy source, while the process would be free of solid wastes such as Spent Potlining (SPL).

A comprehensive technoeconomic study by ALCOA Corporation in order to quantitatively evaluate the economic viability of a carbothermic aluminum process, for a plant capacity of 400,000 metric tons of primary aluminum per year, is reported in,^[6] and its key findings are illustrated in Fig. 1.

Fig. 1 Technical advantages of carbothermic reduction for aluminum production according to the technoeconomic study procured by ALCOA^[10]

The four most remarkable advantages of a carbothermic process are summarized as follows:

1. An identified potential for capital investment reduction due to higher reactor productivity and increase of volumetric processing (as the reaction would take place in a bulk reactor, utilizing all three dimensions). This permits reactor size scale-ups and lower maintenance requirements than the respective ones characterizing conventional electrochemical processes (Hall–Héroult electrolytic cells). According to,^[6] five carbothermic reactors produce an equivalent of 600 Hall–Héroult cells. Thus, considerable industrial reactor sizes and significant economies of scale can be achieved, making primary aluminum mini-mills instead of aluminum mega-plants viable.
2. A tremendous potential for complete elimination of cryolite and toxic fluoride emissions and by-products.

The homogeneous reduction chemistry does not require a molten bath temperature regulator, as carbon is used for the reduction, and high temperature is necessary for the reaction to occur.

3. A significant potential for higher energy efficiency, which can be achieved by only heating the slag toward melting (not electrolysis), by heat-integrated carbothermic reactor design, and by utilizing the valuable CO off-gas enthalpy as a source for thermal and electric energy. The study has determined that a carbothermic process requires 9.6 MWh per ton of Al, while the respective power requirement of a Hall–Héroult process reaches 13.5 MWh per ton of Al. The carbothermic process further offers an option for power cogeneration.
4. An attractive potential for integrating scrap Al recycling in primary Al production plants. A Hall–Héroult process relies exclusively on the use of pure metallurgical-grade Al_2O_3 feedstock and cannot be used to recycle scrap Al; conversely, a carbothermic process can accommodate Al recycling as well as other types of alumina feedstock.

The same technoeconomic study^[6] also includes estimations of cost reductions. A dramatic capital cost reduction of 56% (USD 326 per ton of Al) and an operating cost reduction of 14% (USD 1052 per ton of Al) yield a high total cost reduction of 30% (USD 1378 per ton of Al), as shown in Fig. 2.

Technical Challenges in the Carbothermic Reduction of Alumina

The attractive advantages of carbothermic reduction come at a price of extreme complexity. This complicated, reversible chemical reaction phenomenon has multiple species and phases simultaneously involved in its advance. The main reactants are aluminum oxide (Al_2O_3) and carbon

(C) in various purities and forms, the key intermediates are aluminum suboxide ($\text{Al}_2\text{O}_{(g)}$) and aluminum carbide ($\text{Al}_4\text{C}_{3(s)}$), and the end products are aluminum metal ($\text{Al}_{(l)}$) and carbon monoxide ($\text{CO}_{(g)}$) (a by-product). The complexity of the process is illustrated by the simultaneous coexistence of solid particles (C, Al_2O_3 , Al_4C_3), liquid droplets (Al), and gases (CO, Al, Al_2O) in a high-temperature slag. It should also be noted that, in the end, the liquid aluminum phase produced is in reality an Al–C alloy with approximately 20% mole carbon.^[7] This alloy when cooled will reform carbides, which have to be separated from the aluminum and recycled in the process (reducing the process efficiency).

The key challenges in establishing such a process can be summarized as follows:^[8]

1. The reversibility of endothermic reduction in lower temperatures implies the possibility of back-reaction between Al vapors and CO that quickly reform Al_2O_3 and decrease conversion.
2. Process temperatures are extremely high (ca. 1950°C in melting, 2100°C in reduction), resulting in significant radiation heat losses for most proposed reactor configurations and in nontrivial material selection problems for robust construction and efficient, safe operation.
3. In opposite to usual pyro-metallurgical metal production process, the liquid Al metal phase is lighter than the slag phase, and so it concentrates in the top of the reactor, enhancing volatilization phenomena, hindering continuous feeding, and requiring special reactor design. In the case of the ARP process described in the subsequent section, mass transfer phenomena between the various reactors are crucial for process efficiency and reactor design.^[9–11]
4. Aluminum carbide (Al_4C_3) formation is thermodynamically favored at temperatures below those for liquid aluminum formation, and thus becomes a key intermediate species that inevitably affects process

Fig. 2 Quantitative estimation of carbothermic process potential cost reductions according to the technoeconomic study procured by ALCOA^[10]

balances, chemical equilibrium, and overall alumina conversion as further described in.^[2,8,12]

- Aluminum (Al) has a high vapor pressure and readily evaporates at high temperatures. This is aggravated by a strong tendency for oxidation toward aluminum suboxide ($\text{Al}_2\text{O}_{(g)}$). The combined effect promotes metal loss and thereby reduces reactor efficiency drastically. Despite the fact that carbothermic alumina reduction can only safely occur in an oxygen-free environment (or else the massive production of carbon monoxide could cause an explosion), oxidation of nascent aluminum is inevitable in high-temperature reactor regions, as molten slag is rich in alumina and homogeneous oxidation in the liquid phase is thus possible therein.

Evaporation and oxidation problems are addressed either by aluminum alloy formation or by aluminum vapor recovery toward Al_4C_3 formation that captures the valuable metal and then is re-injected into the molten slag phase to replenish its carbon content *in situ*,^[8] or by moving the process in a gaseous Al production. The latter solution, of course, also requires appropriate engineering to facilitate rapid cooling of large gaseous volumes without allowing back-reactions.

A wide variety of industrial processes and reactor configurations have been proposed in the literature during the last 50 years, according to the excellent review by Motzfeldt.^[12] Review papers about previous corporate experimental efforts that present details of successes and weaknesses have been published.^[13–15] Reactor complexity has evolved along with advances in understanding the complex physical phenomena that occur within multiphase mixtures subjected to extremely high temperatures. Construction material selection and flow controllability challenges remain to the present date.

THE AL–C–O SYSTEM

Carbothermic reduction of alumina to aluminum metal has been extensively investigated: a literature survey reveals numerous studies that have been conducted both at laboratory and at pilot-plant scale.^[5,14–23] Constant progress in understanding chemistry and thermodynamics is evident in these studies. Nevertheless, substantial distance separates the profound understanding of process chemistry from a successful demonstration of reactor design.

Carbon has been identified as an interesting and convenient (thus attractive) reducing agent, since a plethora of experimental studies have demonstrated and documented that numerous (even some relatively low-purity) forms are suitable for advancing the reduction reactions.^[16,18,20,22,23] Charcoal, petroleum coke, and wood chips are only some of the possibilities hitherto explored. A comprehensive study on the effect of porosity, pore size distribution,

and microstructure of the carbon used on the reaction mechanism has been conducted;^[24] a conclusion of this study is that selecting appropriate carbon is crucial, since its microstructure affects reduction considerably.

At a temperature of 2000°C, reaction (2) is hindered by the formation of the aluminum carbides (Al_4C_3) and aluminum oxycarbides (Al_2OC and $\text{Al}_4\text{O}_4\text{C}$), which in the temperature range of 1900°C–2100°C form an alumina-carbide melt (oxycarbide slag) phase. This phase has been published in phase diagrams^[25,26] and is considered to be an ionic melt, described either by an ionic two-sublattice model consisting of $\text{Al}+3$ cations and $\text{C}-4$, $\text{O}-2$ anions^[25] or as an ideal ionic solution of the $\text{AlO}+$, Al_2C^{+2} , AlO_2^- , and $\text{Al}_2\text{C}_2^{-2}$ ionic species.^[26] Figure 3 presents the Factsage phase diagram produced based on the data mentioned earlier.

According to the phase diagram depicted in Fig. 3, a liquid metallic aluminum phase can only be produced at temperatures higher than 2067°C, where the oxycarbide slag phase decomposes forming a carbon-saturated liquid metal along with a gas phase. The thermodynamic calculation for that temperature with a molar ratio of $\text{C}:\text{Al}_2\text{O}_3$ of 2.33 produces a metal phase with 95 wt% Al and 5 wt% C and a gas phase that contains in volume 72% CO(g) , 21% $\text{Al}_2\text{O(g)}$, and 7% Al(g) .

Thus, the complication in the carbothermic reduction of alumina lies in that at “low” temperatures an oxycarbide slag forms prohibiting metal formation, while at higher temperature extensive losses of aluminum in the gaseous phase occur that can reach up to 25% of the total aluminum in the system.^[13,24] The thermodynamic mechanism for the volatilization of the aluminum in the $\text{Al}-\text{C}-\text{O}$ has been investigated in,^[27] where the importance of aluminum suboxide vapor formation is elucidated. $\text{Al}_2\text{O(g)}$ is a metastable chemical species with aluminum in the +1 oxidation state, probably produced as an intermediate product of reaction (2), according to the following equation:

which is thermodynamically possible from 2087°C ($\Delta G(2087^\circ\text{C}) = -241.7\text{ J}$) and is favored with increasing temperature ($\Delta G(2200^\circ\text{C}) = -52.89\text{ kJ}$). The reduction of the aluminum suboxide from carbon

is also thermodynamically possible from 1488°C ($\Delta G(1488^\circ\text{C}) = -40.5\text{ J}$) and is likewise favored with increasing temperature ($\Delta G(2200^\circ\text{C}) = -32.23\text{ kJ}$), yet thermodynamically it is not possible to avoid Al_2O formation in the presence of oxygen and liquid aluminum. The reason is the reaction

Fig. 3 Pseudo-binary phase diagram of Al_2O_3 and C above 1900°C , as calculated by Factsage 7.0 software. ‘Slag’ phase represents the calculated molten alumina carbide/oxy-carbide phase, ‘Liquid’ represents the calculated the liquid aluminum metal (saturated in carbon), ‘Gas’ represents the calculated gaseous phase containing mainly CO, Al, and Al_2O species, and all other species are solids

the occurrence of which is documented in^[28] and is essentially the comproportionation reaction of aluminum species: $2\text{Al}^{[0]} + \text{Al}^{[+3]} \rightleftharpoons 3\text{Al}^{[+1]}$. Metallic aluminum is present in the system either as a liquid Al-C alloy or as aluminum vapors; aluminum in the +3 oxidation state is present in the system as alumina (Al_2O_3) or as aluminum carbide (Al_4C_3) and oxycarbides, while aluminum in the +1 oxidation state can only exist as aluminum suboxide (Al_2O). Thus, in the presence of oxygen atoms in the system, a thermodynamic equilibrium mixture between metallic aluminum, aluminum suboxide vapors, and carbon is formed, preventing the complete reduction of alumina. To comprehend further this mechanism, the effect of oxygen atoms in the system is examined (see Fig. 4).

The Two-Step Reduction Process

As seen in Fig. 4, as more oxygen atoms are removed from the system in relation to Al and C, the moles of liquid metal (Al-C alloy) and the total alumina reduction yield are both increased, reaching their maximum possible values when all oxygen atoms are removed from the system, e.g., when one starts from a 100% aluminum carbide system. This is the thermodynamic justification for staging the carbothermic reduction in a two-step process as described in the latter section.

Step 1–Slag formation:

Step 2–Alloy formation:

With Step 1 reaching thermodynamic equilibrium two-third of the initial oxygen content of the system would be removed (before Al metal is produced), thus allowing in accordance with Fig. 4 the doubling of the liquid Al–C production. These reactions form the two core stages of most developed carbothermic reduction processes, including the patented advanced reactor process (ARP) concept.^[29] Yet due to the formation of the alumina-carbide slag phase (Fig. 3), it is thermodynamically impossible to completely convert all of the alumina to aluminum carbides and therefore thermodynamically impossible to convert 100% of alumina to liquid Al–C metal.

Fig. 4 Calculated aluminum molar speciation and alumina to metallic aluminum reduction yield (dashed line) at 2200°C in system with varying initial aluminum to oxygen atomic ratio and excess carbon. For ratio 3 oxygen atoms/2 Al atoms the initial system is equivalent to the composition of $\text{Al}_2\text{O}_3 + 10\text{C}$, for 2 oxygen atoms/ Al atoms to $0.5(\text{Al}_4\text{O}_4\text{C} + 19\text{C})$, for 1 oxygen atom /2 Al atoms to $\text{Al}_2\text{OC} + 9\text{C}$, and for 0 oxygen atoms/2 Al atoms to $0.5(\text{Al}_4\text{C}_3 + 17\text{C})$ ^[27]

The Gaseous Al Production Process

An alternative to overcoming this problem is moving the system to even higher temperatures where the liquid metal phase is no longer favored and all aluminum is transferred to the gaseous phase. Under such conditions, reaction (5), producing now gaseous Al, is no longer favored as it becomes exothermic, making it thermodynamically possible to completely convert alumina to gaseous aluminum at temperatures above 2500°C. As such temperatures are practically prohibitive for large-scale industrial production, the vacuum carbothermic reduction has been proposed,^[30] whereby decreasing the pressure of the system, the reaction takes place at lower temperatures. As seen in Fig. 5, with decreasing system pressure the formation of $\text{Al}_2\text{O}(\text{g})$ through reaction (5) is suppressed, and complete alumina reduction can take place at lower temperatures. From an energy point of view, one is substituting energy spent in heating with

pumping work, i.e., electricity.^[31] Furthermore, as the metallic aluminum vapors coexist with CO gas, the condensation step becomes crucial in order to avoid re-oxidation of aluminum through back-reactions at lower temperatures.

Metal Solvents and Alloying Elements

The third option for carbothermic reduction of alumina is the hindering of alumina-carbide formation or aluminum volatilization through the introduction of appropriate solvent metals or alloying elements, which alter the activities of species mentioned earlier in the system. In his work, R.A. Frank^[21] investigates the use of a solvent metal to decrease the activity of liquid aluminum metal to such a degree that a thermodynamic interface with the alumina oxide would be possible, suppressing carbide formation. Of the possible systems examined, only Sn, Au, Ag, and Pt produced Al-alloys with no intermetallic compounds, thus allowing postreduction separation of Al metal from the solvent metal. For obvious economic reasons, only Sn could be used in an industrial scale process. If, however, the final product would be an Al-alloy and not a pure Al metal, then Fe, Co, Ni, and Cu could also be considered as metal solvents. Utilizing either Sn or Cu as a carrier metal, it has been proven possible to reduce alumina at temperatures between 1700°C and 1850°C and avoid carbide formation for concentration of aluminum in the metal bath below 9 wt% and 35 wt% for Sn and Cu solvent, respectively.^[22]

Given the very low ratio of Al in the final metal product, an alternative to this route is using an alloying element in the aluminum metal phase, which will reduce carbide formation (but not suppress it altogether). The $\text{Al}_{0.75}\text{-Si}_{0.25}\text{-C-O}$ system in relation to the simple Al-C-O system produces an “enlarged” liquid metal phase and a “diminished” oxycarbide slag phase as seen in the thermodynamic calculation shown in Fig. 6. Still the theoretical maximum liquid aluminum yield is 60% at 2100°C (compared to 40% at 2200°C), as the Si addition does not affect significantly Al volatilization phenomena.^[32]

Fig. 5 Predicted thermodynamic equilibrium $\text{Al}_2\text{O}(\text{g})$ moles at various temperatures and total pressures for systems with initial molar composition $\text{Al}_2\text{O}_3 + 3\text{C}$, using Factsage 7.0 Software^[27]

CARBOTHERMIC ALUMINUM PROCESSES

Historical Background of Carbothermic Processes

The quest for cost-efficient carbothermic reduction technologies is a fascinating chapter of corporate R&D history in its own right, tremendously affected by the energy-intensive nature of aluminum production and the major energy crises that have plagued it over the decades. The concise historical review of previous major R&D efforts^[33,34] and the thorough presentation of candidate reactors and flowsheets^[12] provide detailed information regarding proposed technologies, their successes, and failures. Theoretical concepts for the carbothermic reduction of alumina date back more than a century, while attempts to establish a viable process have been made in the past by major aluminum industries such as REYNOLDS, PECHINEY, ALCAN, and ALCOA.

The patent literature is the primary source of historical details regarding the evolution of carbothermic aluminum reactor concepts, since very few journal publications are available. The comprehensive patent literature overview in the book authored by Motzfeldt et al.^[12] provides a chronological summary of technical innovations and makes an interesting point: the deliberately obscure nature of some patents remarkably hinders subsequent R&D efforts, because patent language and documentation pose challenges to creating a sound design basis.

A total of 30 patents awarded by the U.S. Patent and Trade Office in the years 1946–1984 appear in this patent literature review and employ a variety of daring, often unexplored, ideas. The diversity in patented reactor geometries is striking, in contrast to the standard chemistry. A significant interest in the carbothermic production of aluminum in fact occurred at the end of the 1950s and the beginning of the 1960s: three major aluminum-producing corporations (ALCAN, PECHINEY, REYNOLDS)

undertook large-scale testing projects in order to investigate the potential of carbothermic chemistry, while the major U.S. aluminum producer, ALCOA, had also started smaller-scale carbothermic testing a few years earlier.^[12]

ALCAN was successful in developing a carbothermic aluminum process: the reactions were staged in separate reactor chambers, and electric heating was achieved through the melt. Nevertheless, publications did not appear in the open literature: the process was abandoned due to construction material problems that prevented the development of a full-scale reactor.

PECHINEY entered the quest for carbothermic aluminum processes very early and reportedly experimented on and patented a variety of carbothermic Al reactor from 1955 to 1967. At Grenoble, France, it operated furnaces ranging from 150kW single-phase DC to 2.7 MW, three-phase AC over a five-year period, and produced carbide-saturated metal containing 60% aluminum. Their operations moved to Noguères in 1960. Over the next seven years, Pechiney ran a single-phase DC submerged arc at up to 6 MW, producing 300 tons of carbide-saturated metal, and a 2-MW, three-phase AC open arc, producing about 540 tons of 70%–80% aluminum.^[34] Their carbothermic processes turned out to be cost prohibitive due to high consumptions of alumina and carbon, high vaporization losses, and high energy usage (18.75 kWh/kg).^[35]

REYNOLDS METALS CO. has been among the pioneers of carbothermic research efforts, with an extensive experimental and modeling program undertaken at an Alabama laboratory facility by R. Kibby, L. Ruch, A. Saavedra and N. Richards, lasting for two decades (1971–1990). This detailed investigation resulted in several technical reports and a number of publications evaluating the contemporary state of the art and summarizing their experimental findings on thermal reduction feasibility and reactor design development;^[14–19] these research contributions also identified the serious technical challenges (showstoppers) that

emerged and should be overcome in order to develop a viable and profitable process. Most important of the obstacles hindering the laboratory-scale to industrial-scale transition was the vaporization of aluminum ($\text{Al}_{(l)}$) toward gaseous species ($\text{Al}_{(g)}$, $\text{Al}_2\text{O}_{(g)}$). Reaction staging in distinctly different, separate reactor sections also emerged as a necessity for improving process controllability after testing several proposed reactor configurations: the simplistic approach of combining melting, reaction, and separation in a single compartment may facilitate bench-scale experiments that focus on demonstrating aluminum production, but also hinders the transition from a laboratory-scale prototype to a scaled-up industrial reactor.

In overview, the major research focus has revolved around Cochran's idea of a process in a two-stage reactor,^[36] where at first at temperatures lower than 2000°C an aluminum carbide–alumina slag is formed and then at temperatures higher than 2000°C this slag is further reduced, producing an aluminum–carbon alloy. Cochran's process involved, in the first stage, the creation of a liquid phase (alumina–carbide slag rich in alumina) in contact with solid carbon and alumina. Gradually, all the available carbon is oxidized, producing two-third of the total CO gas and theoretically avoiding aluminum vaporization. By the end of the first stage, a second liquid phase has formed (alumina–carbide slag rich in carbides), which is treated in higher temperatures in order to gradually produce a lighter liquid Al–C alloy phase and the remaining quantity of CO gas.^[36] To achieve efficient phase separation and avoid large aluminum losses in the gaseous phase, precise

control of reactor temperature or precisely tuned multiple reactors are needed, leading to significant reactor design and operational problems.

The ARP and Reactor

Kusik et al. of Arthur D. Little, Inc. published the major conclusions of a thorough technoeconomic assessment study commissioned by the U.S. Department of Energy in order to evaluate the industrial potential of the process.^[6] Therein, the issue of individual technical challenges is illustrated again: the remark that “*several of the subprocesses in the flowsheet have not been reduced to practice, and an opportunity exists to further improve process economics through research and development*” clearly encouraged further pursuit of the ambitious endeavor. ALCOA Inc. thus decided to spearhead research and development (R&D) in the field and initiated collaboration with ELKEM ASA Research (Norway) and Carnegie Mellon University. This industry–academia collaboration resulted in the Advanced Reactor Process (ARP) project, where a novel complex reactor was developed.^[35,37] ARP is a multistage, multiphase, and multi-electrode high-temperature reactor concept for producing aluminum by direct reduction of alumina with a suitable carbon form; continuous operation, attaining high temperatures and recovering molten slag and gas phases were identified as critical operation aspects.^[29] The ARP carbothermic aluminum reactor has four distinct stages, as illustrated in Fig. 7.

Fig. 7 Schematic representation of the conceptual ARP carbothermic reactor proposed for aluminum production^[10]

1. The *first stage* of the ARP carbothermic reduction process is a pre-reduction smelting zone, where slag formation and partial homogenization occur under intense AC electric heating. Open arcs formed by multiple vertical electrode pairs are used to quickly melt the feedstock. Carbon (C) and aluminum oxide (Al_2O_3) pellets are continuously fed to this open electric arc smelter, melt, and their constituents react to form a viscous binary molten slag, which is to be contained under a pressurized inert gas (N_2) atmosphere and simultaneous oil wall cooling. Coexistence of molten slag, Al_2O_3 , and Al_4C_3 particles depends on the temperature profile, and perfect melting is an operation objective that is both hard to achieve and difficult to assess. The slag solidifies against the walls of the oil-cooled furnace and acts as electrical insulation (its structural integrity is thus vital in order to avoid short-circuiting through possible cracks). Another hazard that drives imperative safety expenditures during experiments and operation is the potential reaction of superficial high-temperature aluminum carbide (Al_4C_3) with even the slightest traces of steam (H_2O) trapped or introduced in the reactor: this is a lethal danger, as the ensuing violent oxidation results in a chemical fire (safety and contamination hazard). Localized production of carbon monoxide and aluminum vapors ($\text{CO}_{(\text{g})}$, $\text{Al}_{(\text{g})}$, $\text{Al}_2\text{O}_{(\text{g})}$) is yet inevitable in high temperature areas: these gases are fed to the third stage for Al recovery. The partial reduction of aluminum oxide (Al_2O_3) with carbon (C) to form the Al_4C_3 -rich slag of the first stage is described by the reversible chemical reaction (6).
2. The *second stage* of the carbothermic reactor is the high-temperature reduction smelting zone and the core of the ARP carbothermic reactor, where aluminum is produced. The first-stage molten slag flows slowly into the multi-electrode submerged arc main reactor, where it is heated to a higher temperature: the use of submerged electric arcs is aimed at avoiding localized slag superheating caused by open electric arcs in other patented reactors. Liquid aluminum droplets ($\text{Al}_{(\text{l})}$) and carbon monoxide bubbles ($\text{CO}_{(\text{g})}$) are rapidly generated at hot spots, while the chemical equilibrium can be assisted by further Al_4C_3 injection from the third stage in order to avoid local carbon depletion in intense chemical reduction regions. Carbon replenishment is important because if free carbon is exhausted, the reduction advance becomes problematic, promoting multiphase flow and simultaneous foaming;^[8] conversely, adequate Al_4C_3 injection can shift the chemical equilibrium toward aluminum. The decomposition of the Al_4C_3 -rich slag of the first stage to form the Al-rich metal phase of the second stage is described by the reversible chemical reaction (7).
3. The *third stage* of the carbothermic reduction process is a vapor recovery reactor (VRR), specifically devised to capture aluminum ($\text{Al}_{(\text{g})}$) and aluminum suboxide ($\text{Al}_2\text{O}_{(\text{g})}$) vapors; both are inevitably produced in any high-temperature reactor, as explained in the previous section. Unless Al species are recovered countercurrent to the incoming solid feed, Al loss has a catastrophic impact on process economics by shifting the chemical equilibrium and sharply decreasing the yield. Undesirable vaporization is reduced by staging and feeding gases from both stages to a VRR. Vapors there react with carbon (C) to form aluminum carbide (Al_4C_3), subsequently injected as a solid recycle stream back deep into the molten slag (second stage), replenishing carbon, eliminating the significant metal vapor emission hazard, and maximizing process efficiency. Countercurrent flow of CO can first preheat the incoming C in the upper portion of the VRR; in fact, it exceeds incoming reactant preheating needs, allowing for further energy recovery. Deep injection of Al_4C_3 into the slag is very important in order to ensure continued reduction, instead of adverse enrichment of the superficial aluminum phase in carbon; this possibility is undesirable because it will increase the separation duty of the purification unit (fourth stage). The reactions of aluminum ($\text{Al}_{(\text{g})}$) and aluminum suboxide ($\text{Al}_2\text{O}_{(\text{g})}$) vapors with carbon are as follows:

The unreacted $\text{Al}_{(\text{g})}$ and $\text{Al}_2\text{O}_{(\text{g})}$ vapors become unstable as they rise and react with $\text{CO}_{(\text{g})}$:

4. The *fourth stage* of the carbothermic process is the aluminum flotation and skimming unit: nascent liquid aluminum alloy (of lower density than the slag) produced in the second stage of the process floats forms a top layer and flows through an overflow weir to a single or multiple Al separation tanks that serve as molten metal alloy flotation and skimming units. Entrained solid aluminum carbide (Al_4C_3) particles and dissolved carbon (C) material are removed therein by adding an excess of scrap aluminum: the large enthalpy requirement for scrap metal

melting reduces temperature considerably and thus decreases carbon solubility. Pure aluminum can then be recovered and removed using suitable proprietary technology.

An overview of the ARP prototype system constructed and employed by ELKEM for the experimental campaigns is presented in Fig. 8.^[35]

A number of additional stages appear in the patent,^[29] following the fourth (purification) stage: their purpose varies, but they all address peripheral operations (final heat exchange, metal extrusion, ingot forming, rolling, and casting stages). While these stages are not essential to primary Al production, they form the envisaged concept of an integrated Al plant, which can accomplish primary and secondary Al production simultaneously.

Advanced engineering solutions to all carbothermic aluminum process design, operation, and control problems require high-fidelity mathematical modeling, simulation, and optimization, as technical feasibility depends on interrelated issues that have to be addressed simultaneously. The necessity for accurate process modeling, which considers electrothermic heating, reaction kinetics, and multiphase flow, has been addressed by a number of recent publications authored in Carnegie Mellon University during the ALCOA-ELKEM DOE carbothermic aluminum project.^[10,11,33,38,39]

The ARP resolved some of the technological problems of previous groups (such as heat supply and slag transfer) and introduced the VRR, which not only reduces Al losses in the gas phase but acts as a “self-stabilization” unit, effectively regulating fluctuations in carbon and aluminum content between Steps 1 and 2.

ALCOA-ELKEM calculate the electrical energy requirements for the operation of their ARP to 34.2 MJ/kg

of Al and estimate that the overall capital cost of such a plant would be 30% less than a convention Hall–Héroult plant with equal production capacity.^[35]

Recent advances in these technology have been pursued in both the USA (ATC, Pittsburgh) as well as in Europe (Lista, Norway) toward specific targets, namely the scale-up of the decarbonization step, the experimental process optimization of operating conditions (especially in terms of feed flow rates and electric power intensity), and the detailed investigation of input electric power density (per hearth unit area) effects, toward resolving the attainable process intensification envelope. Further, equally important operability goals include the maximization of Al vapor recovery, and the improvement of process and analytical (instrumentation) equipment toward ensuring accessibility and higher fidelity in data acquisition (temperature, vapor pressure).^[40]

The two foremost technological and engineering problems for which improved solutions are sought toward achieving ARP technology commercialization include the reliable reduction of energy consumption (which must be pursued via enhanced electrode pair efficiency, containment design, reaction staging, and multiphase flow optimization) and the sustainable mitigation of greenhouse gas emissions, possibly by CO₂ capture and sequestration (a goal that can concurrently facilitate the foregoing challenge by preventing adverse effects in the case of the optional electric power generation from CO, an option that can further reduce the plant dependence on fossil energy sources).^[41]

Aluminum–Silicon Alloy Co-Production

An alternative less complicated process to the APR could be the co-reduction of alumina and silica in standard electric arc furnace reactors. The presence of silicon in the

Fig. 8 ARP carbothermic aluminum reactor experimental program: views of the Elkem Hot Box pilot-plant reactor^[35]

system limits alumina oxycarbide slag formation, while the Al–Si alloy formed has very low carbon content. Thus, such a process could achieve the theoretical advantages of the carbothermic reduction of alumina, at the cost, of course, of producing an Al–Si master alloy instead of pure Al.

Historically, Al–Si carbothermic production has been achieved industrially in the past, during the Second World War both in Germany and in Russia. The objective then was to achieve fast and large volume production of aluminum cast alloys for the war industry (airplanes). Yet after the end of the war, these processes were abandoned, and focus was given in producing pure aluminum in centralized primary aluminum plants. Energy consumption and GHG emissions were not an issue at that time, nor were Al-cast alloys a significant part of the market. Today Al–Si master alloys (AlSi25 and AlSi50) are used in casting applications, which account for more than the 30% of the total aluminum demand worldwide for light-weight vehicles and constructions.

Reported experiments in a lab scale DC-EAF have achieved the production of Al–Si alloys with silicon content ranging from 25 wt% to 35 wt% (depending on initial Alumina–Silica ratio) and less than 0.6 wt% carbon.^[32] However, extensive valorization phenomena were observed, signifying the need for a similar VRR as described in the APR processes.

Gaseous Al Production under Vacuum in Solar Furnace

According to the Le Chatelier principle, the extent of a gas producing chemical reaction should be favored by a decrease in the total gas pressure. Thus, under vacuum conditions, the equilibrium of equation

should be shifted to the right and the onset temperature for the gaseous metal production should be significantly lower. The conversion efficiency will depend strongly on the reaction temperature and CO partial pressure.^[42] Experiments in an induction furnace at temperatures between 1400°C and 1800°C with an argon carrier gas flow and an average CO partial pressure between 0.03 to 2.6 mbar have been reported.^[31,43] Accordingly, it has been found that by decreasing the CO partial pressure from 3.5 to 0.2 mbar, the temperature required for almost complete reactant consumption could be decreased from 1800°C to 1550°C. The gaseous Al products were condensed on the relatively cold reactor walls; maximum Al yields were obtained in the region of the condenser where the temperature ranged from 800°C to 850°C. There in the inner layers of the deposits, Al yield was as high as 80% whereas in outer surface layers drops of 100% Al were observed.

Furthermore, estimation of the energy spent as pumping work reveals that if the operating pressure is lower than 0.2 mbar, then the total estimated energy spent for

Fig. 9 Solar reactor for vacuum carbothermic reduction of alumina at the Weismann Institute of Science in Israel^[30]

heating and pumping exceeds the actual energy (which is almost twice the respective theoretical one) spent in the established Hall–Héroult process.^[31,44]

For the vacuum process to be sustainable, the process heat must be supplied through a renewable source such as through the use of concentrated solar radiation in solar furnaces, and compromise between temperature and pressure is obligatory to decrease electrical energy consumption for pumping.^[45] Such a solar driven process was demonstrated in a 10-KW capacity solar tower achieving 90% aluminum conversion with an average reaction temperature of 1525°C and a CO partial pressure of 0.04–0.06 mbar.^[43] The prototype reactor is seen in Fig. 9. While such process is far from large-scale industrial application, it is worth noting that morphology of the produced pure aluminum depends on the temperature at the deposit site, thus allowing production to range from liquid aluminum in hot condenser zone to nanoparticle size aluminum at cold condenser zones.

CONCLUSION

The carbothermic reduction of alumina has an identified potential for drastic reduction of the fixed and operation costs of a greenfield investment, due to a remarkably high theoretical volumetric productivity. Furthermore, it is more environmentally benign, avoiding use of fluoride compounds and in principle much more energy-efficient than conventional electrochemical methods, since the costly electrolytic reduction is effectively avoided by using carbonaceous reactants and following a direct chemical reduction pathway. Electric energy is again required, but to a limited extent and exclusively for heating (or pumping) purposes.

The interest in carbothermic reactor technology has been driven by a justified expectation of significant cost advantages in both capital and operational costs. However, while the theoretical foundation of process chemistry is sound and significant steps have been made in understanding and modeling the Al–C–O system at high temperatures, process implementation remains cumbersome. Side and back-reactions, volatilization phenomena, and intermediate products complicate the process engineering.

A recurring pattern that emerges in the study and comparison of schematics in many patents and publications is the attempt to achieve the carbothermic reduction of alumina to aluminum in a two-stage reaction process, taking place in connected reactors. The ALCOA-ELKEM ARP endeavor has been certainly successful in terms of demonstrating the technical feasibility of operating the novel and intricate multistage and multiphase reactor, with a concerted exploration and explicit identification of the operability and efficiency challenges. The ARP project resulted at an energy cost for aluminum production of 9.5 kWh/kg and with an estimated overall capital cost of such a plant to be 30% less than a convention Hall–Héroult plant with equal production capacity.

Alternative processing ideas proposed are aimed at achieving single-stage reduction processing and include introducing metal solvents and/or alloying elements to suppress back and side reactions as well as moving the system toward gaseous aluminum production. The direct production of Al–Si master alloy and the introduction of renewable energy in the form of concentrated solar radiation in the process mark significant innovations yet are still far removed from industrial application.

Abstract

The effect that modification of cast Al-Si alloys exerts on the thermal and electrical conductivities is presented. The work was conducted by casting a series of samples in a rig that promotes uni-directional solidification to vary the level of microstructure refining, which was assessed by the secondary dendrite arm spacing. The alloys were prepared in a furnace and poured into the rig after adding different amounts of strontium to modify the aspect of the aluminum-silicon eutectic. Measurements were conducted on as-cast and heat-treated specimens. The electrical conductivity tests were referred to the International Annealed Copper Standard. Thermal conductivity of the different samples was obtained by comparing it with that of a high-purity aluminum sample. It was found that either value of conductivity depends on the degree of modification and by heat treating, whereas other microstructural parameters exert a secondary effect.

Keywords: Casting; Conductivity; Modification; Refining.

INTRODUCTION

The automotive industry is one of the major driving forces for improving processes and products, because their everyday more stringent demands for performance and weight savings are passed downstream to their suppliers. As result of this, the use of aluminum alloys in combustion engines has increased, and more importantly, the development of novel processes and design techniques has allowed for the reduction in size of the engines without impairing their performance. Cylinder heads are just one example of the successful replacement of cast iron by aluminum alloys to reduce the weight of the engine and to comply with environmental regulations imposed in different countries.^[1] These pieces are designed to withstand critical conditions, because they are subjected to high pressures and temperatures within the combustion chamber, as well as the thermal cycling resulting from starting up and turning off the engine. Heat extraction has to be efficient otherwise the component may be subjected to excessive thermal loads that will modify the mechanical properties of the alloy, leading to its catastrophic failure.^[2–4]

Previous studies have pointed out that thermal stresses and fatigue in an engine can be reduced if the thermal conductivity of the material is increased.^[5–7] Unfortunately, this property is difficult to measure and its value is normally related with the electrical conductivity. Figure 1 shows such a case for a series of cast alloys, independently of their chemical composition, heat treating, and microstructural condition,^[8] and, despite the fact of the scatter, it is possible to obtain a direct correlation between both properties.

The aim of this work is to present the effect that different microstructural and processing characteristics exert on the thermal and electrical conductivities in a cast Al-Si-Cu alloy used in the manufacture of various components of the engine block.

EXPERIMENTAL PROCEDURE

A series of experimental heats were prepared in a 250 kg gas-fired furnace. The melt was degassed with nitrogen before adding master alloys of titanium to refine the grain size and strontium to modify the Al-Si eutectic aggregate (Table 1).

Fig. 1 Correlation between thermal and electrical conductivities for a series of cast aluminum alloys^[8]

Table 1 Chemical composition of the experimental heats

Heat	Si	Cu	Fe	Mn	Mg	Zn	Ti	Sr
A	7.84	3.15	0.582	0.439	0.219	0.542	0.071	6
B	7.54	3.42	0.619	0.421	0.312	0.735	0.141	56
C	7.39	3.49	0.577	0.407	0.337	0.750	0.104	94
D	7.72	3.54	0.635	0.422	0.349	0.760	0.067	166
E	7.57	3.38	0.589	0.403	0.300	0.717	0.155	243

Note: Contents in mass %, except Sr that is in ppm.

Liquid metal was poured at 740°C into alumina molds designed to impose a one-direction thermal gradient by a steel-plate chill at their bottom.^[9] The ingots were sectioned to characterize the microstructure at different positions. Cylindrical samples of 50.8 mm in height and 19.7 mm in diameter were machined with their cylindrical axis normal to the solidification direction to assure that the electrical and thermal conductivities were measured on a constant microstructure. The former one was obtained with an apparatus calibrated to the International Annealed Copper Standard (IACS) following the American Society for Testing and Evaluation (ASTM) E1004 standard.

Thermal conductivity was evaluated with respect to that of a high purity aluminum sample. The arrangement shown in Fig. 2 was used. It consisted of a hot plate and a cooling reservoir containing iced water. The sample under study was placed on top of the reference one. Both samples had a series of holes of 1.6 mm in diameter drilled to their centers into which type K thermocouples were introduced. Thermal contact between the thermocouples and the samples was enhanced with the use of conducting grease, and between the samples with the use of silver paint. One-dimensional heat flow, required to evaluate the conductivity, was assured by wrapping the samples with ceramic fiber of 25 mm in thickness (not drawn to scale in Fig. 2). The readings from the thermocouples were obtained with a 12-bit data logger that had an accuracy of $\pm 0.7^\circ\text{C}$; the confidence of the temperature readings given by the thermocouples was in the interval of $\pm 1.1^\circ\text{C}$. The

Fig. 2 Experimental setup used to determine the thermal conductivity

time derivative (dT/dt) was obtained by fitting a second-degree polynomial through an odd number of points from the cooling curves; dT/dt was evaluated at the midpoint of the odd data.^[9] This derivative was plotted as a function of temperature to obtain the steady-state value (T_s) by extrapolating to $dT/dt = 0$.

The samples were polished following conventional metallographic techniques using emery paper of different grits and finishing with alumina of 1 μm in size. Porosity was evaluated on polished samples using an image analyzer; the values were averaged from 10 measurements done on a 1 cm^2 of area. The microstructural characteristics were evaluated on samples etched with a solution of 5% hydrofluoric acid. Secondary dendrite arm spacing (DAS) was obtained by the mean linear intercept technique in at least 300 arms. The degree of modification is identified with the numbers 1–5 (that indicate no modification to overmodified) was assessed by direct comparison to charts of the American Foundry Society.^[10,11]

Some of the specimens were heat treated to stabilization (T7) or annealed (O). The former consisted of solubilisation for 8 h at 490°C, cooling in water at 90°C, and aged for 4 h at 250°C. The annealed samples were left to cool down in the furnace after holding them for 8 h at 490°C.

RESULTS

The chilling effect that causes the steel plate at the bottom of the ingot molds promotes the reduction in the spacing between the secondary branches of the dendrites up to a height of around 150 mm, as the spacing remains constant above this height (Fig. 3). The increase in the cooling rate may also affect the level of modification, as the only samples that had a level 5 of modification were found close to the bottom of ingots in which the amount of Sr was

Fig. 3 Porosity and DAS as a function of distance from the chilled end of the experimental ingots

above 90 ppm; correspondingly, the samples that exhibited the level 1 of modification were above 80 mm and had only 6 ppm of Sr. The solidification rate did not appear to affect the porosity in a consistent way. Figure 4 shows the microstructures typical for different levels of modification that were obtained with various amounts of Sr.

Figure 5 shows the temperature–time plots of one of the tests (in this case, a sample treated to the T7 condition from the third heat). The data were obtained using the logger described in the previous section. Evaluation of the thermal conductivity in the alloyed sample is made after assuming that the one-dimensional heat flow is established:

$$q = -k \frac{dT}{dx}, \quad (1)$$

where q is the heat flow, k is the thermal conductivity, and dt/dx is the thermal gradient within the piece. In the present case, if the flow within the two-sample system is constant,

$$k_0 \left. \frac{dT}{dx} \right|_0 = k_1 \left. \frac{dT}{dx} \right|_1, \quad (2)$$

where the subindices 0 and 1 refer to the high-purity and alloyed aluminum samples, respectively. For this study, k_0 was set equal to 240 W/mK.^[12,13]

Equation 1 is only valid when a steady state is attained and the change of temperature as a function of time is zero. Figure 6 shows the method used to determine the temperature at the steady state (T_s) for one curve from Fig. 5. The time–temperature data were fit to a series of second-degree polynomials to obtain the instant rate (dT/dt); the steady-state temperature is then obtained by fitting a straight line through the last portion of the dT/dt data points, so T_s is defined as the value when $dT/dt = 0$. Once the temperatures at the steady state are obtained, they are plotted as a function of distance, and the thermal conductivity of the sample under study is found by comparing it to that of the one for the high-purity aluminum (Eq. 2). An example of such a case is shown in Fig. 7 for two samples cut from an ingot from heat A in their as-cast and heat-treated (T7) conditions (their thermal conductivities were calculated to be 126 and 135 W/mK, respectively).

The validity of the procedure used is proved in Fig. 8 where the electrical and thermal conductivities are plot together with the best fit line from Fig. 1:

$$k_T = 24 + 3.3k_E \quad (3)$$

where k_T and k_E are the thermal and electrical conductivities expressed in terms of W/mK and % IACS, respectively. It can be appreciated that the specimens in which the eutectic aggregate was modified to a higher degree exhibited higher conductivity.

DISCUSSION

Figure 9 compares the values of the electric conductivity in the as-cast samples with those obtained in samples annealed and aged to the T7 condition; heat treating results

Fig. 8 Correlation between the thermal and electrical conductivities for the alloys under study. The broken line is the best fit from Fig. 1

Fig. 9 Comparison of the electrical conductivity in the as-cast samples and those that were heat treated (annealed and aged)

in the increase in conductivity of 2.20% IACS on average for the annealed samples and 3.44% for the aged ones. Figure 10 shows the corresponding comparison for the values of the thermal conductivity of as-cast and aged samples. The effect of heat treating is similar to that observed in Fig. 9, as aging increases the conductivity in 12.83 W/mK on average.

The effect that different microstructural characteristics exert on the thermal and electrical conductivities was analyzed. Figures 11 and 12 show the effect that DAS exerts on the electrical and thermal conductivities, respectively. Reduction in DAS results in the increase in conductivity in either condition, but the effect is buried by that of modification, as the samples with coarser DAS show a low degree of modification. Figures 13 and 14 show the effect that porosity exerts on either the electric or the thermal conductivity; the trend is similar, as the

Fig. 10 Comparison of the thermal conductivity in the as-cast samples and those that were aged

Fig. 13 Effect of porosity on the electrical conductivity of samples in the as-cast and aged conditions

Fig. 11 Effect of DAS on the electrical conductivity of samples in the as-cast and aged conditions

Fig. 14 Effect of porosity on the thermal conductivity of samples in the as-cast and aged conditions

Fig. 12 Effect of DAS on the thermal conductivity of samples in the as-cast and aged conditions

Fig. 15 Effect of modification on the electrical conductivity of samples in the as-cast and aged conditions

Fig. 16 Effect of modification on the thermal conductivity of samples in the as-cast and aged conditions

increase in porosity degrades the values of conductivity. Figures 15 and 16 show the effect that the modification of the eutectic aggregates exerts on the electrical and thermal conductivities.

It is difficult to separate different microstructural effects, because the chilled ends of the ingots had a finer DAS, as result of the shorter solidification times, but at the same time, they exhibit a higher level of modification, due to the increase of heat extraction and solidification rate. The porosity is also reduced at the chilled end as the alloy solidifies there first and will have liquid metal to compensate the loss in volume due to contraction.^[9–11,14–16]

The dependence on the degree of modification and either the thermal or electrical conductivity, as well as their increase during heat treating, can be explained in terms of the semiconductor nature of silicon.^[10,15] As the degree of modification increases, the morphology of the silicon particles within the eutectic aggregate changes from acicular plates to rounded particles,^[14,15,17,18] which reduce the thermal and electrical barriers. The difference in behavior between annealed and stabilized samples can be explained in terms of the precipitation of a second phase, which consists of small dispersed particles in the T7 material, in comparison with larger particles encountered in annealed samples, which will hinder conductivity to a higher extent.

CONCLUSIONS

The experimental technique developed to evaluate the thermal conductivity of cast aluminum alloys was able to evaluate the effect that various microstructural characteristics exert on this property, as well as the changes produced during heat treating.

It was found that the degree of modification is the parameter that exerts a higher influence on both thermal and electrical conductivities. The effect that DAS exerts on conductivity is smaller, but this may be consequence to the

way the material was cast, which affected at the same time modification, porosity, and DAS.

The results show a close relationship between both types of conductivity and the morphology of the eutectic, although the latter was assessed in terms of the description from a chart.

The increase in conductivity in heat-treated samples can be explained in terms of the spheroidization of Si plates of the eutectic aggregate. The increase in conductivity was higher in the T7 samples, and this can be attributed to the dispersion of smaller second-phase particles.

Casting Designs

Henry W. Stoll

Northwestern University, Evanston, IL, United States

Abstract

This article addresses issues and practices associated with aluminum casting design. The focus is on aluminum casting design generally including expendable molds and permanent molds. Topics addressed include: casting processes, design related casting defects, mechanical property variation, geometry and material process interactions, thermal post processing, tooling, design related cost drivers, casting design guidelines and concurrent engineering.

Keywords: Concurrent engineering; Defects; Design; Geometry; Guidelines; Tooling.

INTRODUCTION

As manufactures seek to reduce weight and cost of products, aluminum alloy casting has emerged as an “optimal” material and manufacturing process choice in many situations. This is because aluminum casting offers the important advantage of being able to produce lightweight, highly complex functional shapes quickly and easily. Cost is reduced because numerous parts and complex construction and processing steps typically associated with built up structures and weldments can be replaced by a single cast part. Weight is reduced because the lightweight aluminum alloy can be located where it is needed and because sections can be thinner since load does not transfer across part interfaces, i.e. through fasteners or welds. To harvest these advantages, there are certain desirable goals that the aluminum casting designer should strive for.

1. **Maximize Functionality:** The engineer should design as much function as possible into the casting while also ensuring that the casting will successfully withstand the service requirements for which it is intended. This means that a single cast part may take the place of many individual separate parts, eliminating assembly operations, reducing weight, and frequently improving the overall structural integrity. For example, the numerous separate parts (formed sheet metal components plus rivets and other hardware) in a built-up aircraft access door can be replaced by a single monolithic aluminum casting.
2. **Optimize Manufacturing Characteristics:** In casting, the part being produced and the tooling used to produce the part interact in complex ways, which effect the quality, cost, and lead-time of the casting. Because of these complex interactions, part

geometry not only determines the functionality and structural integrity of the casting, it also determines the mold construction, mold filling and material solidification processes involved in producing the casting. These processes in turn affect cycle time, casting quality, and material properties such as yield strength, ultimate strength, and fatigue resistance. Casting geometry must therefore be determined based on both functional and processing requirements. Casting manufacturability is optimized by considering the foundry, tooling, and secondary processing (e.g. machining, heat treating, etc.) needs early in the design process, before design decisions become fixed and therefore difficult and costly to change.

3. **Minimize Material Usage:** The minimum volume of metal that will satisfy the structural, functional, appearance and manufacturability requirements of the application is usually the best choice. Metal casting offers two unique and very desirable design advantages that facilitate material minimization: (1) metal mass can be located exactly where it is needed; and (2) complex, three-dimensional geometry is readily created.

To achieve these goals, it is essential that the aluminum casting designer have a good working knowledge of the following subjects.

- The advantages and limitations of the various casting processes used for producing aluminum castings.
- Types of geometry related casting defects, their causes, and methods of prevention.
- The service and casting characteristics of aluminum alloys and their suitability for each of the various casting processes.

- Thermal processing of aluminum castings (e.g. heat treating, welding) and its effect on production and service performance of the casting.
- Pattern, permanent mold, and die casting die construction and operation.
- Sources of casting cost and design considerations that drive these costs.
- Sources of machining cost and design considerations that drive these costs.
- Mechanical properties of cast aluminum alloys.
- Structural design principles and practices.
- Concurrent engineering methods and practices.

This chapter discusses the issues and practices associated with aluminum casting design. The focus is on aluminum casting design in general including both expendable molds (e.g. sand casting, investment casting, etc.) and permanent molds (e.g. die casting).

CASTING PROCESSES

Casting is a manufacturing process in which molten metal alloy is poured or otherwise caused to flow into a shape that approaches that of the finished component. In creating the casting, the melt is conducted to the cavity in a highly controlled manner using a system of channels, reservoirs, and other flow elements, which we will collectively refer to as the *rigging system*. The shape is provided by the *mold*, which is, in essence, a cavity having the negative shape of the component and sized to compensate for dimensional changes (shrink) that occur as the alloy solidifies and cools to room temperature. The mold may be expendable or permanent. An *expendable mold* is used only once and is typically broken into pieces to free the solidified casting. A *permanent mold*, on the other hand, is intended to be reused over and over again and is designed to release the solidified casting by opening and closing. In this section, we briefly overview the various casting processes to provide the background needed to discuss casting design. See Chapter 15 for a more in-depth discussion of casting process details.

Rigging System

In most casting processes, the rigging system performs two major functions: (1) fill the mold cavity with molten metal; and (2) feed additional molten metal to the casting to compensate for shrinkage that occurs as the casting solidifies. The typical rigging system is made up of a variety of different elements or features that allow it to perform these functions (Fig. 1)

The filling function is performed by the *running system*, which includes the pouring cup, sprue, runners, in-gates, and other channeling and flow control elements. For example, in the sand casting process, molten alloy is

Fig. 1 Typical rigging system elements

poured into the *pouring cup*, which is a receptacle sized and shaped to accommodate the stream of metal and smooth its flow. The *sprue* transports the metal to one or more *runners*, which in turn distribute the metal to the cavity. Typically the sprue is conical in shape to help minimize or reduce turbulence and mixing of air with the metal flow. The runners generally have large cross-sections and are often shaped to streamline and slow down the flow and deliver it to various regions of the mold cavity with a uniform flow rate. The runners are connected to the cavity by *gates* that control the flow of metal into the cavity. Typically, gates have reduced cross-sections to control the metal flow and to allow easy separation of the rigging system from the solidified casting. A *well* at the base of the sprue may also be provided to retain contaminants such as refractory materials that may have been washed off the mold walls during pouring as well as non-metallic compounds formed by the molten metal reacting with air.

The *feeding system* helps avoid flaws such as porosity and shrinkage cavities by locating feeders at one or more locations around the casting (Fig. 1). *Feeders* (also called *risers* or *feeder heads*) are reservoirs of molten metal that continue to supply the casting with metal until it is completely solidified. Feeders are typically located at “chunky” regions of the casting that are likely to require additional metal supply as they solidify. In addition to feeders, detail casting geometry can help eliminate casting defects as discussed throughout this chapter.

Expendable Mold Casting Processes

Expendable mold casting includes a variety of casting processes such as sand casting, shell molding, vacuum molding, the lost foam process, and investment casting. In all of these processes, the expendable mold is prepared by consolidating a refractory material (sand or other refractory powder or slurry) around a *pattern* that defines the shape of the mold cavity (Fig. 2). Typically, the pattern will also define the shape of the rigging system, although, in some specialized cases, the runners and gates may be

Fig. 2 Steps in the production of a sand casting

manually added during molding. The processes differ in that, in some cases the pattern is reusable and in others, it is expendable.

Sand casting, shell molding, vacuum molding, and other similar casting processes employ reusable patterns. To be *reusable*, the pattern is typically made of a material that is durable enough to permit repeated consolidation of the refractory and is shaped to allow withdrawal from the consolidated refractory mold. To allow withdrawal of the pattern from the mold, a *parting plane* is selected that conveniently divides the cavity into two or more parts. Surfaces that are perpendicular to the parting plane are sloped (i.e. have *draft*) to facilitate easy pattern removal. In addition, the pattern dimensions are increased (*shrinkage allowance*) to compensate for shrinkage that occurs as the solidified casting cools to room temperature.

Since the reusable pattern imprint forms the cavity, the pattern creates the external shape of the cast part. Internal features such as recesses, internal cavities, holes, and other undercuts are formed by cores. A *core* is a full-scale model (modified by the shrinkage allowance) of the internal feature that is typically made of sand formed into the desired shape by a *core box*. The cores are placed in the mold cavity after the pattern is withdrawn and are supported by *core prints* (nesting holes provided by the pattern), and also by *chaplets* (metal supports that ultimately melt into the casting) in some cases, that allow the molten metal to flow between the core and the mold wall. In some cases, cores may also be necessary to produce a desired “zero” draft external surface, depending on the parting line selected.

Casting processes, such as the lost foam process and investment casting process, employ expendable patterns. An *expendable* pattern is typically destroyed as part of the casting process. In the *lost foam process* (also called the expanded polystyrene casting process, the lost pattern process, and evaporative foam process), for example, the pattern is made of polystyrene foam that vaporizes when the molten metal is poured into the mold. The polystyrene pattern typically includes the rigging system and may also contain internal cores (if needed), thus eliminating the need to fabricate and place individual cores in the mold. Also, since the pattern itself becomes the cavity, considerations of draft and parting plane can be ignored. The pattern can be made in a variety of ways depending on the quantity of castings to be made. For one-of-a-kind castings,

the foam may be manually cut and assembled to form the pattern. For large production volumes, on the other hand, an automated molding operation can be utilized.

In *investment casting*, a pattern made of wax is coated with a refractory material to make the mold. The wax is then melted out of the mold prior to pouring the molten metal. Investment casting is capable of very intricate shapes, close dimensional control (± 0.076 mm), good surface finish, and is a net shape process since no subsequent machining is normally required. Because the pattern is expendable, there is no need to remove the pattern so cores and draft are not needed, and the only limitation on shape is that the ceramic shell must be removable after the casting has solidified. The disposable wax patterns are readily produced in large quantities by injection molding into metal dies. Note that, in this case, some draft may be necessary to permit removal of the wax pattern from the metal die.

Permanent Mold Casting Processes

In *permanent mold casting*, the mold is made of metal (usually steel or cast iron) and is designed to open and close at the parting plane. The cavity and rigging system are machined into the mold halves to provide accurate dimensions and good surface finish. A prime requirement of permanent mold casting is that the solidified casting be readily removed from the mold cavity. This requires generous draft on surfaces that are perpendicular to the parting plane. In addition, cored features such as undercuts and transverse holes must not prevent opening of the mold and/or ejection of the solidified casting. When the cavity is filled under gravity or low pressure feed, sand cores may be placed in the permanent mold to produce desired interior features while still allowing the mold to open and close and the part to be readily ejected. This approach is often referred to as *semipermanent mold casting*. In high production applications and/or when filling pressure is high, more costly and complicated moveable metal cores must be used. Also, in more mechanized applications, *ejector pins* are necessary to remove the solidified casting from the mold.

A variety of different permanent mold casting processes are used. *Gravity-fed* permanent mold casting is similar to expendable mold casting processes such as sand casting

except the mold is made of an appropriate permanent material. In *low pressure permanent mold casting*, the mold is located directly above the melting or holding furnace and metal is fed by air pressure into the mold cavity. In *die casting*, metal is forced into the mold cavity under moderate to high pressures. In the *cold-chamber die casting process* typically used for aluminum alloys, molten metal sufficient for one shot is transferred into the shot chamber and then injected by a plunger into the mold cavity.

Finishing Processes

Finishing processes are required to clean the solidified casting and prepare it for use in its intended application. For example, the rigging system (e.g. gates, runners, risers, sprue, etc.) must be removed by either breaking off (brittle materials) or sawing and grinding (more ductile materials). Remnants of the gate as well as flash must then be removed in additional trimming operations. Inspection is another important finishing process. If defects are found in the finished casting, they can often be repaired by welding.

After the casting has been cleaned and inspected, it may be further processed in a variety of ways. These operations, which are often referred to as secondary processing, might include stress relieving, heat treating, hot isostatic pressing (HIP), welding, machining, joining, painting, and plating. The final surface finish of most aluminum castings usually falls into one of three broad categories: as cast, mechanically finished, and/or chemically finished. The as cast surface finish of aluminum castings is often good enough for use without further treatment in many applications. In other applications, the appearance or quality of the surface finish can be enhanced by mechanical or chemical treatments. The most common mechanical finishing methods include abrasive blasting, ball burnishing, wire brushing, tumbling, and buffing.

Surface appearance and corrosion resistance may be further enhanced by chemical conversion coatings (e.g. Alodine or Irridite processes) or by anodizing. Chemical conversion processes enhance appearance by imparting a translucent color ranging from gold to a gray-green, but these coatings are not very durable or wear resistant. In the anodizing process, an anodic coating of aluminum oxide is applied to the aluminum casting by an electrochemical process similar to electroplating. Anodized finishes are more durable and wear resistant, but also reveal casting defects such as pinhole porosity and dross inclusions, so closely controlled foundry conditions and precise alloy composition is essential.

CASTING PROCESS SELECTION

The selection of a particular casting process to produce a specific part is governed by a variety of factors and considerations. Paramount among these is the geometric

configuration and design features of the casting, which essentially determine the feasibility of the different processes. When more than one casting process option is feasible, the choice will then usually depend on size (weight), production quantity, cost targets, and budget constraints. Also, depending on the application, functional requirements such as soundness, pressure tightness, mechanical properties, and so forth may strongly affect the process selection.

Tolerance capability is typically better for permanent mold casting processes because the metal mold is usually more accurate. Also, the metal mold (often combined with higher pressure and therefore better thermal contact) extracts heat faster, which produces better mechanical properties due to increased solidification rates and the finer micro structure that results. Operator skill also tends to be less for permanent mold processes since these processes are usually more mechanized. Expendable mold processes such as sand casting, on the other hand, are capable of producing complex external and internal shapes and are also suitable for relatively small production quantities. Also, expendable mold casting processes tend to have less porosity defects provided that good casting technique is used.

Unit cost is highly dependent on production quantity because tooling cost (patterns, molds, etc.) must be distributed over the number of castings shipped. Typically, expendable mold casting involves more manual labor and worker skill and is better suited for lower production quantities. For low production quantities, the casting process involving the least tooling investment will typically result in the lowest unit cost. However, unit cost is often high for low production quantities because of the additional manual labor involved. With higher production quantities, unit cost decreases since tooling cost is amortized over the higher number of parts and more mechanization of the process can be justified. Permanent mold processes such as die casting, however, typically require very high production quantities to offset the very high initial tooling investment required.

DESIGN RELATED CASTING DEFECTS

Casting defects occur for many reasons. Some are foundry or process related. For example, common sand casting defects include sand blow, pinholes, sand wash, scabs, penetration, mold shift, core shift, and mold crack. Others are common to casting processes in general and result because of undesirable interactions that occur between the casting geometry, alloy, and process. We refer to these as *design related casting defects* because they involve the casting geometry and can often be avoided by appropriate casting and rigging system design.

Porosity

Porosity is a casting defect that typically appears as a network of small voids distributed in various regions of the

casting. If the porosity can be seen by the naked eye during radiographic inspection, it is referred to as *macroporosity* while porosity that requires magnification to be seen is referred to as *microporosity*. Porosity in cast aluminum is caused by gas bubbles that get trapped in the solidifying alloy (*gas porosity*) and by voids that form between dendrites due to solidification shrinkage effects (*shrinkage porosity*). Gas bubbles are caused by hydrogen that precipitates out as the molten metal solidifies due to the dramatic change in solubility and by air that is entrained during high velocity flow of the molten metal during filling of the mold cavity. Shrinkage pores develop when the interdendritic flow of molten metal becomes blocked. The size of shrinkage porosity often depends on solidification rate since dendrites are larger with slower solidification. Such pores can also be enlarged by trapped gas. Gas pores are usually fairly spherical in shape while shrinkage pores typically have more irregular and elongated shapes.

Macroscopic porosity degrades both static and dynamic properties of the casting by reducing cross sectional area and by acting as internal stress risers and crack initiation sites. In addition, macroporosity can detract from functionality and/or appearance if it occurs on a critical surface or if machining or other finishing operations expose it. Also, porosity can be a potential problem if pressure tightness is a concern.

Shrinkage Cavity

A *shrinkage cavity* is a large irregularly shaped void in the solidified casting. This defect occurs when the supply of molten metal feeding a region of the casting is either depleted or is unable to flow sufficiently to compensate for solidification shrinkage of the alloy. Such defects typically occur in *hot spots* which are regions of the casting that cool more slowly than surrounding regions and are therefore cut off from a supply of molten metal.

Misruns

The term *misrun* is used to describe situations where a region of the mold cavity is not completely filled with metal. Misruns usually occur because the molten metal solidifies prematurely or is too thick or viscous to flow into a particular feature or region of the casting. For this reason, geometry related misruns usually occur in mold cavity cross sections that are too thin.

Cold Shuts

As molten metal fills the mold cavity, the liquid flow often divides into two or more streams as it flows around cores and other obstacles. *Cold shuts* occur when the portions of the metal flow rejoin but fail to fuse completely. Lack of fusion usually results because of premature freezing. Oxidation of the flow surfaces can also prevent complete fusion.

Hot Tears

A *hot tear* is a separation of the metal that appears as a tear or crack. Hot tearing occurs when the mold prevents the casting from contracting naturally as it solidifies and cools. Unyielding mold walls that constrain contraction of the cooling casting induce tensile stress in the casting. Tearing or cracking then occurs in regions where the tensile stress exceeds the strength of the solidifying material. Avoiding hot tearing is complicated by the fact that the solidifying alloy gains strength as it cools.

Warping and Distortion

Stress develops when thinner, less massive regions cool faster and therefore become stronger and more rigid than adjacent regions that are more massive and therefore slower cooling. This stress causes deformation that is “frozen in” as *residual stress* when the whole casting gains sufficient rigidity. Residual stress may cause warping and other undesirable distortions of the cooled casting. Also, subsequent machining of the casting or other processing can relieve these stresses resulting in additional warping.

Metallurgical Defects

Metallurgical defects include inclusions of non-metallic particles, oxide films, and secondary phases that form during solidification. *Inclusions* are insoluble non-metal aggregates that are suspended in the liquid aluminum. They may form during solidification or before solidification begins. Also, in some expendable mold processes, they may also be washed off of the mold wall and/or introduced in other ways during the casting process. Inclusions act as stress concentration points and reduce dynamic properties. They can also be detrimental during machining by causing excessive tool wear and breakage as well as unacceptable surface defects.

Oxide films, which form on the surface of the molten metal as it flows through the rigging system and fills the mold cavity, are similar to inclusions and are of particular concern in aluminum casting. If the film folds over on itself as a result of turbulent flow or “waterfalling,” the effects can be particularly damaging. *Waterfalling* occurs when molten metal falls to a lower level during mold filling.

Secondary inclusions or *second phases* can form as the primary alloy phase starts to freeze causing the remaining liquid to progressively concentrate in various solutes. Like inclusions and oxide films, second phases act as stress raisers and can nucleate cracks if they have the proper size and shape.

Mechanical Property Variation

Mechanical properties such as yield and ultimate strength of the casting alloy may vary with location in the casting.

This scatter in property values is often due to variation in solidification rate that occurs in different regions of the casting. For example, “chunky” regions of the casting will cool more slowly than thin, less massive regions. Regions that cool more slowly typically have coarser grain structure and therefore less strength than regions that cool more quickly and therefore have finer grain structure. Also, for long freezing range alloys (i.e. alloys whose constituent components solidify at significantly different temperatures), micro-segregation of the alloy composition may occur which can also result in variation of mechanical properties. Another source of variation is the presence of casting defects such as porosity.

Uncertainties in casting strength can be of great concern in the design of safety-critical castings such as those used in automotive suspension components and in aerospace applications. In industries such as aerospace, these uncertainties are accounted for by using both statistical design allowables and a casting factor.^[1] The static strengths of alloys that can be used in airframes are given in^[2] and are based on rigorous statistical analysis of strength testing data. The *casting factor* is used to increase the margin of safety:

$$S_D = P/CF \quad (1)$$

where S_D is the design strength, P is the design allowable, and CF is the casting factor. The value of the casting factor to be used in a particular casting design is determined by part criticality and inspection to be made on the casting. In addition to x-ray, penetrant and visual inspections, requirements may include periodic destructive testing and testing sample coupons. Inspection requirements become increasingly strict with decreasing casting factor. For example, the smallest casting factor that can be used in the design of a critical part is 1.25. Use of this CF value requires 100% visual, magnetic/penetrant and x-ray inspection of all castings plus destructive testing of three castings. A comprehensive discussion of casting factors is given in.^[3]

GEOMETRY/MATERIAL/PROCESS INTERACTIONS

Design related casting defects are caused by undesirable interactions that occur between the casting geometry (including the rigging system), the alloy, and the casting process. Understanding how casting geometry, the material in both its liquid and solid phases, and the casting process interact provides the insight needed to specify the best casting geometry from a function, form, and fabrication point of view. In the following, we explore several geometry/material/process interactions that are pivotal to good casting design. Many of the terms and discussion are based on.^[4] For a more in-depth discussion of these topics, the reader is referred to this reference.

Fluid Life

Fluid life or *fluidity* refers to the ability of the molten alloy to fill the mold cavity, flow through thin narrow channels to form thin walls and sections, and conform to fine surface detail. In addition to temperature of the molten metal, fluid life also depends on chemical, metallurgical, and surface tension factors. Therefore, the fluid life of each alloy is different. For example, aluminum 356 is considered to have excellent fluid life whereas the fluid life of aluminum 206 is only fair to good. Misruns and related casting defects can be avoided by proper consideration of the fluid life of the particular casting alloy to be used. Fluid life determines the minimum wall thickness and maximum length of a thin section. It also determines the fineness of cosmetic detail that is possible. Hence, knowing that an alloy has limited fluid life suggests that the part should have softer shapes (i.e. generous radii, etc.), larger lettering, finer detail in the bottom portion of the mold, coarser detail in the upper portions of the mold, more taper leading to thin sections, and so forth.

Solidification Shrinkage

Shrinkage occurs in three distinct stages: liquid shrinkage, liquid-to-solid shrinkage, and solid shrinkage. *Liquid shrinkage* is the contraction of the liquid before solidification. *Liquid-to-solid shrinkage* or *solidification shrinkage* is the shrinkage that occurs as the disconnected atoms and molecules of the molten metal form into the crystals of atoms and chemical compounds that constitute the solid metal. *Solid shrinkage* is the shrinkage that occurs as the solid metal casting cools to ambient temperature. Although liquid shrinkage is important to the metal caster, it is not an important design consideration. Solidification shrinkage and solid shrinkage, on the other hand, are extremely important and must be carefully considered during casting design.

Different alloys have differing amounts of liquid-to-solid shrinkage (e.g. aluminum 356 has little shrinkage tendency while aluminum 520 has a large shrinkage tendency). Most importantly, there are three different types of solidification shrinkage: directional, eutectic, and equiaxed.^[4] In alloys that solidify directionally, solidification moves along predictable pathways determined by the casting geometry and thermal gradients in the mold. For example, solidification will typically begin at the mold wall and move perpendicularly toward the center of the part. This is called *progressive* solidification. Solidification will also begin in cooler regions where the mold surface area to metal volume ratio is large and travel toward the hotter regions of the casting. This is called *directional* solidification. The key is to configure the part geometry so that directional solidification can occur before progressive solidification shuts off the source of liquid metal supply (the riser). Without proper pathway geometry (e.g. risering

and tapering), voids (shrinkage cavities) or pores due to isolated internal shrinkage can result.

In eutectic-type solidification, the liquid metal cools and then solidifies very quickly all over. This behavior minimizes internal shrinkage and the need for risers and makes this type of alloy the most forgiving of the three. Eutectic-type materials that have very little solidification shrinkage often require no risering at all. As discussed previously, *risers* are reservoirs of molten metal that continue to supply the casting with metal until it is completely solidified. The key geometric concern for eutectic-type solidifying alloys like aluminum 356 which have small but appreciable solidification shrinkage is to ensure that the avenue of liquid metal supply stays open and functioning all the way to final solidification.

In addition to solidifying both progressively and directionally from the mold walls, alloys that exhibit an equiaxed solidification behavior also begin to solidify throughout the liquid, forming “mushy” regions consisting of equiaxed islands of solid. These equiaxed islands can block the avenues of liquid metal supply making these alloys difficult to feed. One way to mitigate this effect is to decrease the length of the mushy zone by increasing the thermal gradient (e.g. increase the solidification rate by adding chills, etc). Alternatively, the casting can be designed to have small thermal gradients. In this approach, thermal mass is spread out and distributed uniformly throughout the casting. This causes the shrinkage to be distributed as microscopic pores throughout the volume of the casting. In both approaches, the effect on mechanical properties is greatly minimized by the small size, rounded shape, and uniform dispersion that result.

Pure aluminum and short freezing range alloys that have a high percentage of aluminum will typically exhibit directional solidification behavior whereas eutectic alloys such as aluminum-silicon (11.6% Si) exhibit the desirable eutectic-type solidification. Long freezing range aluminum alloys, on the other hand, are more likely to exhibit equiaxed-type solidification.

Solid Shrinkage

Solid shrinkage is often called “pattern maker’s shrink” because the tooling must be properly sized so that the part will shrink to the desired final size and shape upon cooling. Solid shrinkage is critical for two important reasons. First, the shrinkage must be predicted and then built into the patterns/dies and corebox dimensions. If this is not done correctly, then the tooling will need to be modified iteratively to achieve an acceptable production casting. This adds time and cost to the design cycle and introduces quality risk in the final product. Second, as the casting cools, it may not be able to shrink uniformly because some regions are stiffer than others. This can result in undesirable residual stresses and/or undesirable distortion and warpage. Creating casting geometry that makes shrinkage

predictable and that avoids residual stress and warping is therefore highly desirable.

Slag/Dross Formation

Slag is typically composed of liquid nonmetallic compounds (usually fluxed refractories), products of alloying, and products of oxidation in air. *Dross* refers to non-metallic compounds produced primarily by the molten metal reacting with air. Aluminum alloys are quite sensitive to slag/dross formation and are therefore more likely to contain non-metallic inclusions. In addition to process and quality control techniques, part geometry can be used to dramatically reduce the likelihood of non-metallic inclusions. For example, because slag/dross are buoyant in aluminum, the probability of having an inclusion in a critical machined surface can be reduced by designing the part so that these surfaces are located in the lower portion of the mold. Similarly, the rigging system can be designed to control the amount of oxidation that occurs due to turbulent flow and entrained air and to avoid waterfalling.

Fluid Flow

Another key geometry/process interaction involves the flow of molten metal into the mold cavity. As mentioned previously, turbulent flow through gates and other channels can effect the amount of oxidation and consequent dross formation that occurs. Another consideration is the force generated by the molten metal as it flows into the mold cavity and the turbulence of the flow in the cavity since both of these effects can displace cores and erode mold walls, especially sharp edges and high detail features. Steep thermal gradients can also arise due to fluid flow. If the flow separates to pass around cores and other features and the joins together again, weld lines (cold shuts), non-metallic inclusions, and other flaws can occur due to cooling and oxidation of the flow front. In order to minimize undesirable effects of fluid flow, the casting must be poured slowly. Unfortunately, this gives the molten metal more time to oxidize and increases process cycle time. Undesirable interactions due to fluid flow effects can often be reduced or eliminated by designing the casting geometry and rigging as a system.

Heat Transfer Considerations

The geometry must also be selected with an understanding of the heat transfer conditions involved. If the geometry is such that the heat cannot escape, a hot spot is likely to occur. For example, narrow peninsulas or tight corners of mold material surrounded by molten metal will get hot very quickly and as a result, solidification of the molten metal in these regions will be slower than surrounding regions. This creates the possibility of “hot tears” or “shrinkage pulls” because the hotter material will have less tensile

strength and is therefore less able to resist internal forces that develop due to solidification and solid shrinkage. Shrinkage cavities can also form because liquid metal supply paths close off before the material in the region of the hot spot is fully solidified.

Just the opposite situation occurs when sharp corners or narrow peninsulas of molten metal are surrounded by mold material. In these cases, the molten metal cools and solidifies very quickly. This is generally a desirable situation. However, if cooling is too rapid, it can cause cold cracking due to stressing of the solidified skin or thin region by solidification shrinkage occurring at a slower rate in more massive adjacent regions. Also, difficult to machine or undesirable material properties may result from rapid cooling of some alloys.

Geometry/Alloy Interactions

It is important to note that each aluminum alloy has its own unique set of casting characteristics. In most cases, it is the combination of material properties possessed by a particular alloy that determines the most desirable casting geometry. For example, aluminum 356 has excellent fluid life, and more eutectic type than directional type solidification. This combination of properties makes this alloy well suited for precision casting and permits fine detail and thin walls everywhere. However, although still relatively small, solidification shrinkage is significant enough to warrant consideration especially with respect to risering, section size, and feeding pathways.

Aluminum 514 is at the opposite end of the spectrum. This alloy has relatively poor fluid life and large, directional type solidification shrinkage. This combination of material properties makes 514 less casting friendly. As a result, careful attention to casting geometry is essential. Because of its poor fluid life, fine detail and thin sections are difficult. Most importantly, because of its large solidification shrinkage, feeding of the casting is a great concern. Risers need to be large and the geometry must be carefully designed to ensure proper feeding of the casting. Also, because of its unfavorable combination of properties, aluminum 514 requires softer shapes (i.e. large radii, rounded shape, large lettering, no sharp detail) compared to casting friendly materials such as aluminum 356.

Aluminum alloys, such as 356, exhibit good casting characteristics largely because of their relatively high silicon content. High silicon content is, in fact, the main difference between widely used aluminum casting alloys and other aluminum casting alloys. The addition of silicon reduces the solidification temperature range and produces more eutectic type solidification. This improves castability by increasing fluid life and feeding and reducing hot tearing. Aluminum alloys having lower silicon contents (e.g. almost all of the alloys in the 2xx.x, 5xx.x, 7xx.x, and 8xx.x groups), on the other hand, exhibit much less friendly casting characteristics. Hence, geometry /material

interactions for these alloys must be carefully considered during the early stages of design if sound castings that transition quickly into production is to be obtained.

ALLOY SELECTION

Alloy selection is a pivotal determination that must be made early in the casting design. In many respects, alloy selection is just as important as the structural design of the casting since a good structural design may give unsatisfactory service if it is cast from an unsuitable alloy. As discussed in the previous sections, it is essential that the designer not only consider physical and mechanical properties when selecting a casting alloy, but also the casting process and foundry characteristics and how these are likely to interact with the detail geometry of the casting. Hence, alloy selection should be based on all of the following considerations.

- The ability of the alloy to meet service and code requirements.
- The suitability of the alloy for the casting process.
- The size and complexity of the casting configuration.
- The minimum section thickness required.
- Heat treatment considerations. Will heat treatment be required? Or, can a self-aging or non-heat treatable alloy be used?

It is the designer's responsibility to select the alloy that will best satisfy these requirements. In most situations, some intelligent compromise must be made since it is unlikely that any one alloy will be able to satisfy all requirements equally well. However, with a good understanding of the needs of the design, together with knowledge of how the detail casting geometry, casting process, and alloy interact, it is possible to design the casting so that all demands are effectively balanced. Achieving this balance is the goal of good casting design.

THERMAL POST-PROCESSING

Aluminum castings may be further processed thermally after casting to improve mechanical properties and correct defects.

Heat Treatment

Heat treatment is used to modify or change the alloy structure and mechanical properties and is typically specified to provide one or more of the following benefits.

- Improved mechanical properties.
- Internal stress relief.
- Improved dimensional stability.

- Improved machinability.
- Improved corrosion resistance.

In general, no one single time and temperature cycle will produce all of these beneficial effects, so, as with alloy selection, some intelligent compromise may be necessary.

An aluminum alloy whose tensile strength is improved by thermal treatment is said to be *heat treatable*. Generally, alloys containing significant amounts of copper or magnesium are heat treatable. Alloys for which thermal treatment has no effect on tensile strength are termed *non-heat treatable*. However, even though heat treatment does not improve strength in these alloys, it can be used to improve other properties. In those alloys that are heat treatable, essentially two types of heat treatment are possible: *solution heat treatment* and *precipitation hardening* (also referred to as *aging*). In non-heat treatable alloys, the heat treatment processes used are *annealing* and *stress relieving*.

In *solution heat treatment*, the casting is heated rapidly and uniformly to a temperature as close to the melting point of the eutectic as possible (typically 800–1000°F). The casting is held (soaked) at this temperature for a specified number of hours and then quenched in hot water. *Quenching* is the rapid reduction in temperature of the casting to roughly 180°F. A uniform rate of quenching is required to prevent the development of localized areas of thermal stress and distortion. If straightening of the casting due to quench distortion is necessary, it should be performed as close as possible to the time of quenching (within 24 h or less) since the casting will typically gain strength as it ages, even at room temperature. In some cases, this completes the heat treatment. However, for the majority of castings that have been solution heat-treated, additional aging or precipitation hardening is required.

Aging or precipitation hardening is the part of the thermal treatment that actually increases the strength of the alloy under the influence of heat. The strengthening process, which is referred to as *artificial aging*, is carried out by heating the casting to some intermediate temperature (usually 300–500° F) and soaking it for a period of time (2 h to three weeks depending on temper). It is important for the designer to know that some aluminum alloys will age naturally (*natural aging*) at room temperature without the application of heat. Natural aging in service can result in a loss of ductility and dimensional stability. Also, some aluminum casting alloys can overage (*overaging*) if held too long at an elevated temperature resulting in a loss of tensile strength combined with an increase in ductility and dimensional stability. This is one of the reasons why the temperature of the service environment is an important consideration in aluminum casting alloy selection.

There are several basic thermal treatments or tempers applied to castings. These are summarized as follows. See Chaps 2 and 5 for a more in-depth discussion of heat treatment.

- F-Temper: as cast condition with no special control of thermal conditions in the process.
- O-Temper: annealed condition. Applied to castings that have been heat treated to improve dimensional stability or ductility.
- T4-Temper: solution heat-treated, quenched, and naturally aged.
- T5-Temper: cooled from an elevated temperature and artificially aged. This temper improves mechanical properties and dimensional stability, especially for castings intended for high temperature service environments.
- T6-Temper: solution heat-treated, quenched, and artificially aged. This heat treatment develops optimum mechanical properties and good ductility and dimensional stability.
- T7-Temper: solution heat-treated, quenched, and overaged. Overaging improves the dimensional stability of the casting, but is accompanied by some reduction in tensile properties.

The most desirable mechanical properties are obtained by use of both solution and aging treatment (T6 and T7). However, the feasibility of this thermal processing depends on the casting size and configuration, so it is important to plan on this processing in the design stage.

Hot Isostatic Pressing (HIP)

In some applications where fatigue failure and/or pressure tightness is a concern, it is desirable to have essentially 100% of theoretical density. In *hot isostatic pressing*, the casting is placed in a pressure vessel (autoclave) and an inert gas (e.g. argon) is introduced. The gas is then heated to increase its pressure and to put pressure on the casting. The heat also softens the casting allowing internal voids to collapse under the pressure. If the HIPing is performed properly, no residual voids will remain in the material except for surface connected porosity. This type of porosity cannot normally be healed by HIPing and must be weld repaired. Also, if the porosity is relatively large, HIP will form small dimples on the surface of the casting that may also require weld repair. Because HIPing is a thermal process (as well as a pressure process), it can modify the microstructure and hence the casting properties if not carefully planned and performed. HIP treatment is relatively inexpensive and has made it possible to use alloys that do not solidify pore free (e.g. long freezing range equiaxed alloys) in fatigue-critical and other high-integrity applications.

Weld Repair

Weld repair is a common practice for filling surface connected porosity, post-HIP surface depressions, and other defects such as cold shuts. In general, a casting may not be

welded without permission of the customer. Therefore, to simplify weld repair, the designer should clearly specify the maximum size, number and location of possible defects that could be repaired by welding. Most importantly, areas where welding is not allowed should be clearly specified. It is also very important for the designer to fully understand how the welded area will influence mechanical properties such as fatigue resistance and ultimate strength. Repair welding should be performed prior to any heat treatment and final non-destructive testing.

TOOLING CONSIDERATIONS

In casting, tooling is used to create the mold cavity and cores and to hold the whole package together so that molten metal can flow and solidify to form the cast part. The tooling differs considerably however, between permanent and expendable mold casting. In permanent mold casting processes, the tooling consists of a steel or cast iron mold (or die) and moving and non-moving steel cores. In expendable mold casting, tooling is used to shape the cavity (pattern) or to form the pattern (investment casting). Tooling is also used to mold cores that are placed in the cavity to form undercuts and internal features.

Tooling is also similar in many respects. In all cases (both expendable mold and permanent mold), the mold is divided into two halves so that the final casting, core, or pattern can be withdrawn (Fig. 3). When the mold halves close, the core and cavity, or two cavities meet, producing the air space into which the molten aluminum alloy flows (Fig. 3(a)). From the inside, the mating junction between the mold halves appears as a line. This line also appears on the casting and is called the *parting line* or *parting plane*. Similarly, all surfaces that are perpendicular to the parting plane must be tapered in the direction of mold opening so that the solidified casting, core, or pattern can be withdrawn easily from the mold. This taper, which is commonly

Fig. 3 The mold is divided into two halves so that the final casting, core, or pattern can be withdrawn, (a) The mating junction between the mold halves defines the parting plane, (b) Draft provides ejection clearance upon mold half separation, (c) With draft, walls and other features cannot be exactly perpendicular to the parting plane

referred to as *draft*, allows the molded part to break free by creating a clearance as soon as the pattern starts to be withdrawn or the mold starts to open (Fig. 3(b)). Any feature that prevents the mold from opening or the pattern from being withdrawn is referred to as an *undercut*. In permanent molds that are mechanized, *side action* (camming) is used to move a core so that the mold can open and/or the part ejected (Fig. 4). In expendable molds and semi-permanent casting processes, manually placed sand cores are used. In all cases, cores are expensive and introduce complexity and quality risk into the process.

Detail geometry of the cast part determines, to a large extent, cost of the tooling as well as time and effort required to design and construct the tooling. In the following, we explore how casting geometry impacts tooling design and construction for several major casting processes.

Tooling for Sand Casting

Tooling for sand casting processes can be made in many different ways depending on the detail geometry of the part and on cost, quality, and lead-time requirements. Major decisions include the fabrication method, material, and tooling approach to be used. Traditionally, patterns and core boxes have been manually fabricated from hand-crafted prototypes of clay, wood, plastic or other materials. This time consuming process can now be performed using CNC machining processes to generate the tooling by removing material from a starting workpiece (subtractive process) or by using one or more FFFF (Fast Free Form Fabrication) processes to generate the tooling by building it up one layer at a time (additive process).

FFFF methods can be used in a variety of different ways to facilitate the rapid fabrication of foundry tooling for different casting processes (Fig. 5). Layered Object Manufacturing (LOM) and StereoLithography are typical of the several FFFF processes that are commonly used for rapid tooling. In the LOM process (Fig. 6), the part or tool is built-up by laser cutting sheets of paper in the shape of the part cross-section and stacking and gluing the sheets together to form the three-dimensional part. In StereoLithography, the layers are created by using a laser to selectively photo cure a special kind of resin, called a

Fig. 4 In die-casting and mechanized permanent mold casting, undercuts that prevent mold opening require core slides

Fig. 5 Using FFFF processes to fabricate foundry tooling for casting presents a myriad of possibilities

photopolymer, that has the property of turning solid under the influence of certain wavelengths of light. For the shape of each slice to be known, FFFF processes must be computer controlled using a CAD solid model representation of the part geometry. FFFF methods can greatly reduce tooling lead-time and cost, however it may also introduce additional error. For example, the LOM process requires tessellation of the solid model and smoothing and sealing of the finished tooling (Fig. 6). See^[5] for further discussion of rapid tooling methods.

With the addition of rapid tooling as a pattern fabrication method, there are three basic categories of fabrication methods to consider: manual, FFFF, and CNC machining. Each of these categories has a range of choices. For example, there are several FFFF processes that might be used depending on the capability of the particular pattern shop involved. In addition to patterns, core fabrication must also be considered. Cores can be fabricated directly or molded using a core box. Typically, a core box would be used when higher production quantities are required. Like patterns, either the core itself or the core box can be fabricated using manual, CNC machining, or FFFF methods.

Sand casting tools can generally be fabricated from a large variety of different materials. Frequently used materials for reusable patterns include mahogany or other wood, urethane plastics, synthetic materials, metals and FFFF materials. Mahogany and other woods are particularly well suited for manual fabrication because they are

easy to work with. Urethane plastic offers high quality and strength. Synthetic materials such as renboard are popular because of their durability and machinability. Metals (mainly aluminum and steel) are used when long tool life is a concern. FFFF materials range from polymer, paper, nylon, ABS plastic, wax, etc. depending on the particular FFFF processes used.

The *tooling approach* relates to the way the mold cavity is created. Commonly used tooling approaches include single or loose patterns, gated patterns, match-plate (mounted) patterns, and cope and drag (top and bottom) patterns. A *loose pattern* is essentially a model of the cast part that incorporates the allowances and core prints necessary for producing the casting. Such patterns are generally made of wood, but can also be made of metal, plaster, plastic, wax, or any other suitable material. Relatively few castings are typically made from any one loose pattern since hand molding is practiced and the casting production is slow and costly. The parting surface may be hand formed and gating systems are hand-cut in the sand. Drawing the pattern from the sand, after rapping it to loosen it from the sand, is also done by hand. As a result, dimensional accuracy of the casting can vary from casting to casting and is generally not very good. Loose patterns are best suited for producing prototype castings. *Gated loose patterns* are an improvement on ungated loose patterns. The rigging system is included as a part of the pattern to eliminate hand-cutting of these features. This type of pattern can produce small quantities of castings with a more rapid molding cycle.

In a *match-plate pattern*, the cope and drag portions of the pattern are mounted on opposite sides of a wood or metal plate conforming to the parting line. Rigging systems are almost always attached to the plate. Match-plate patterns are typically used with some type of molding machine and are capable of producing large quantities of small castings. This type of pattern has improved dimensional accuracy and higher production rates compared to loose patterns.

In the *cope and drag* tooling approach, cope and drag portions of the pattern are mounted on separate plates. This greatly increases the production rate by allowing the cope and drag halves of the mold to be made separately on different molding machines. Separate cope and drag plates are costly, however. Also, cost is increased because the separate pattern plates require accurate alignment of the

Fig. 6 LOM based rapid tooling process for sand casting

two mold halves by means of guide and locating pins and bushings in flasks.

In practice, each tool build approach has its own set of advantages and disadvantages. Generally, the dimensional accuracy, tool life, and production rate increase as the selected tooling approach moves from loose patterns to cope and drag plates. But tooling fabrication time and cost also increase. Hence, the tooling approach selected will generally depend on the production volume required in addition to dimensional accuracy and lead-time.

Cost, lead time, and quality (e.g. tolerances) of sand casting tooling depends on the fabrication method, tool material, and tooling approach selected. These decisions, in turn, depend to a great extent on the detail casting geometry involved. Often, minor geometry decisions can inadvertently eliminate low cost and/or time efficient options from consideration. When possible, the designer should work closely with the foundry and tool builder early in the casting design process to insure that detail geometry decisions do not unnecessarily constrain tooling choices.

Tooling for Investment Casting

Investment casting offers tremendous design freedom. Complex shapes that would be too costly to machine can be produced quickly and economically as investment castings. From a design perspective, it is important to remember that the pattern for investment casting is injection molded. The designer should therefore observe good design for injection molding practices. These include well-located, straight parting line, generous draft, avoidance of undercuts, and the use of generous fillets and radii wherever possible. The molds for making the wax patterns can be fabricated in a variety of ways such as those discussed for sand casting. Therefore, as in sand casting, the designer should strive to avoid making geometry decisions that constrain tooling options unnecessarily.

Tooling for Permanent Mold Casting

Permanent casting molds are generally made of cast iron and are frequently coated with a layer of sodium silicate and clay or other insulating material. The molds are typically preheated to 150–200°C prior to pouring. Auxiliary water cooling or radiation pins may be used to cool heavy sections. Proper venting of the mold cavity is essential to avoid misruns. Only simple part geometry is suitable for permanent mold casting. If complicated coring is necessary, then semi-permanent molds that use sand cores should be used. Draft and parting line selection are also key design considerations.

Tooling for Die Casting

Die casting involves the high pressure injection of molten metal into a split metal die. Tooling for die casting is very

complicated and therefore costly, even for simple shapes. Very high metal injection pressures (up to 69 MPa) must be withstood for many thousands of cycles. Large dies are commonly cooled by channeling water behind heavier sections and through cores. The solidified part is ejected after the die opens by ejector pins that bear on the casting face. Following the molding process, the casting is trimmed using a hardened steel trimming die shaped to match the cast shape. Trimming typically involves the removal of in-gates, gates to overflow pads, parting line flash, and flash in cored holes and openings. The following general considerations are important in creating detail geometry of the die cast parts.

1. **Coring:** Undercuts that prevent die opening and/or part ejection require core slides (Fig. 4). This adds cost and complexity to the die and can increase cycle time for the process.
2. **Draft:** Draft is required to get the part out of the die and off of cores. Therefore, walls and other details cannot be perpendicular to the parting line unless expensive core slides are used (Fig. 3).
3. **Part Ejection:** After a part has been cast, it must be removed from the die. Typically, the part is mechanically ejected by ejector pins or by more costly options such as ejector sleeves or rings. Ejector pin location can be critical and should be carefully chosen to avoid stress concentration, poor appearance (ejector pins can leave unsightly marks on the part), and distortion of the part. Also, ejection is facilitated by generous draft, which decreases ejection force and helps avoid ejection problems.
4. **Die Modification:** In die casting, air and die lubricants often become entrained and trapped in the solidified casting due to the high injection velocities and solidification rates employed. This results in microporosity and uncertain mechanical properties that may not be predictable beforehand. When this is the case, it may be necessary to modify the die after it has been hardened. Ribs and other similar features can be incorporated into an existing hardened die by using electrical-discharge-machining techniques. When the use of ribs to strengthen the casting is a consideration and mechanical properties are uncertain, it may be better to under design initially, test sample castings, then add strength if necessary by removal of die steel until the optimum combination of mechanical properties and casting material conservation is achieved. This is preferable to over designing and having to lighten the die casting later by welding the die, which is a costly and life-limiting procedure. It should be noted that “test and fix” approaches should be avoided where possible by observing good casting design practices, computer simulation and an effective concurrent engineering design process.

5. **Concurrent Engineering:** After being machined, the dies must be hardened by heat treating, which makes subsequent alterations difficult. Therefore, the die caster should be involved early in the design process and agreement with the die caster on the producibility of the finalized best design should be obtained before the die is designed and fabricated.

DESIGN RELATED COST DRIVERS

The cost of a casting is determined by its size, configuration, and detail geometry. Size and configuration are usually dictated by the functionality and service requirements of the part. Given these requirements, the casting designer must specify suitable detail geometry that satisfies these requirements at the lowest possible cost. *Design related cost drivers* are detail geometry design decisions that strongly effect the cost to design, tool, and produce the casting. Important design related cost drivers for casting include the following:

- Parting line.
- Amount of draft.
- Number and complexity of undercuts.
- Number, size and complexity of separate cores.
- Section shape (e.g. junctions, ribs and webs, holes and pockets, bosses and pads).
- Casting tolerance.
- Trimming.
- Secondary processing (e.g. machining, heat treating, surface treatment, etc.).

The major sources of cost for most casting processes include tool cost, material cost, and production cost. Unit cost for a casting is given by the following expression:

$$\text{Cost/Part} = \frac{C_T}{N} + V C_M + \frac{C_H t_{\text{cycle}}}{Y} + \frac{C_D}{N} \quad (2)$$

Where,

C_T = total non-recurring tooling cost (\$)

C_M = material cost (\$/in³)

C_H = machine cost including labor and recurring tooling expenses (\$/hr)

C_D = total development cost (\$)

N = lifetime number of good castings made using the tooling

V = total material volume including rigging system (in)

t_{cycle} = cycle time to cast, trim, and finish one casting (hr)

Y = process yield (usable parts/ N)

It is important to note that Eq. 2 is very comprehensive in that it includes all the costs associated with each cost source. Tooling cost for sand casting, for example, would include the cost of the pattern and core boxes, the cost of trimming dies or other finishing tools, the cost of machining fixtures, and so forth. Similarly, cycle time includes

all of the cycle times associated with making the casting. For sand casting, this includes the cycle time for forming the mold cavity, molding the cores and placing them in the mold cavity, readying the mold for pouring and pouring the casting, cooling and breaking it out, trimming the rigging system, performing finishing and inspection operations, and setting-up and finish machining the casting. Cycle time also includes material handling time and other non-value-added time. Likewise, the machine cost and process yield corresponding to each cycle time is used in the production cost calculation. Finally, it should be noted that development cost includes all of the engineering cost associated with designing and testing the casting including design revisions and tooling changes.

Equation 2 clearly indicates what should be done “by design” to reduce cost:

- Design to minimize tooling cost.
- Design to minimize material cost.
- Design to minimize cycle time.
- Design to maximize process yield.
- Design to minimize development cost.

Achieving these objectives requires an understanding of how the design related cost drivers influence total cost. How each design related cost driver effects cost is discussed as follows.

Parting Line. The parting line establishes many aspects of both the part geometry and the process. The parting line choice effects the length, width, and depth of the mold halves which essentially establishes the pattern size and shape and the complexity and cost of the mold. In die casting and other pressure fed casting processes, the projected area established by the parting plane determines the clamping force required and therefore the size of the casting machine. This in turn effects tooling cost, machine cost, and to a lesser extent cycle time. To minimize part cost, the parting line should be selected very early in the design process. The goal should be a parting line that keeps tool complexity to a minimum. A planar parting line is preferable to a non-planer parting line. Also, when possible, a parting line that places the whole part in one mold half can greatly reduce tool cost and alignment and registration requirements across the parting line are avoided. The parting line can also be an important constraint if FFFF or CNC pattern building methods are being considered.

Draft. Generous draft is highly desirable for low part cost. Minimal draft, especially when combined with deep draws, increase tool cost because tooling surfaces become more critical and special surface treatments may be necessary. This increases cycle time and tooling cost. Minimal draft increases cycle time in permanent mold casting because the casting must be stronger and therefore cooler before it can be reliably ejected. It also increases cycle time in expendable mold casting because more care must

be exercised in withdrawing patterns and so forth. Yield may also be adversely effected when difficult part ejection or pattern withdrawal results in damaged parts or molds. A difficulty that is commonly encountered when applying draft to a part is the creation of unacceptably heavy walls. One remedy is to use parallel draft which allows the wall sections to be kept uniform (Fig. 3(c)).

Undercuts. Anything that can be done to avoid undercuts or reduce their complexity will reduce tooling cost and development time. In die casting, undercuts require moving cores, which greatly increases tooling cost. Moving cores can also increase cycle time since the cores must move before the mold can open and/or the part can be ejected. The best way to avoid undercuts is to select the parting line wisely. In addition, it is often possible to design so undercuts can be created using simple tooling without the need for expensive side actions (Fig. 7).

Separate Cores. In sand casting and permanent mold casting, separate cores must be placed in the mold cavity before each part is cast to produce internal features. Expendable cores must be molded using core boxes which increases cost and cycle time. The designer should therefore strive to eliminate separate cores whenever possible. This is especially true for long, thin, and small cores, which can cause core and casting scrap. As always, judgment is required however, since coring may be desirable if it makes it possible to provide sections of uniform thickness or helps to minimize machining.

Section Thickness. Castings are composed of various geometrical features that integrate together to define the overall shape and functionality of the casting. Each section feature, such as walls, junctions, ribs and webs, holes and pockets, bosses and pads, and so forth, involves a wall or section thickness. Hence, just about every aspect of the casting appearance, functionality, quality, and manufacturability relates to, affects or will be influenced by the section thickness selected for individual casting features. From a cost standpoint, it is safe to say that section thickness impacts all of the cost sources in one way or another. The most obvious is material cost since section thickness directly effects the material volume of the casting with less volume, and therefore less material, being more desirable. Also, less material results in faster cooling and potentially shorter cycle times. At the same time, thinner sections require longer fluid life, more injection pressure, and/or

time to fill the mold. If the section is too thin, yield may be adversely effected because flow is restricted and the part will not fill out properly (e.g. misruns). Also, in die casting, high injection pressure can result in flash or highly stressed parts. In addition, thinner sections can require more mold detail and closer core/cavity alignment and fit which will increase tooling cost. Thick sections, on the other hand, cool slower, shrink more, and have more risk for sink marks and shrink cavities. They also are more difficult to feed and are therefore more likely to contain porosity. This is especially true for long freezing range equiaxed-type alloys. Hence, in addition to increasing material cost, unnecessarily thick sections can also decrease yield and increase cycle time.

Shrinkage occurs as the molten alloy cools in the mold cavity to form the solidified casting. Since thin sections cool and contract more rapidly than thick sections, stress can be induced when thick sections that are adjacent to thin sections constrain shrinkage of the thin section. As a result, the thin sections may tear to relieve the stress, or they may deform plastically without tearing. If they do not tear, warpage and shape distortion can occur when the casting is removed from the mold. Varying section thickness, therefore, introduces a quality risk that can be avoided by employing a uniform wall thickness everywhere in the casting. By using a uniform wall thickness, thermal mass, and therefore shrinkage, is the same everywhere.

Tolerance. Tight dimensional and form tolerance specifications increase tooling cost and reduce cycle time and yield. This is because there are many hard to control factors associated with casting processes. For example, in sand casting, equipment, metal, and sand can vary from lot to lot and foundry to foundry. Metal temperature, cooling time, and cooling conditions can vary. This, together with slight differences in core placement, mold hardness, shrinkage, internal stress, and so forth, introduce additional hard to control part to part variation. In addition, tight tolerances require more precise tooling, close process control, and often 100% gaging with resulting scrap. Therefore, whenever possible, component tolerances should be relaxed as much as possible. Also, where possible, the part should be designed so that critical dimensions do not cross the parting line to minimize positional accuracy required between mold halves.

Trimming. After the solidified casting has cooled to room temperature, the rigging system together with any flash and remaining gate and riser material must be removed. This is a time consuming (especially if performed manually) and costly (especially if trimming dies and other tooling is used) process. The rigging system also adds material cost and material handling cost. The need for trimming can be reduced by designing the casting so that a minimal number of risers and gates are needed and by designing so that the gate and riser contacts can be located in non-critical easy to access areas. Also, locating gate and riser contacts so they don't interfere with machining fixture

Fig. 7 In some situations, a hole or depression in the side wall of a part can be cast without the need for side action cores

targets will reduce trimming time, the cost of the fixture, and possibly machining cycle time because the fixturing will be easier and more consistent.

Secondary Processing. Many castings are heat-treated, finish machined, anodized, plated, painted, stress relieved, and so forth after casting. It is important that requirements and constraints imposed by secondary processing be considered early in the casting design. Often, the most effective way to do this is to involve experts in these processes early in the design before irreversible design decisions have been made.

CASTING DESIGN GUIDELINES

Casting design involves the specification of the overall configuration (i.e. overall shape and arrangement of features) of the casting as well as the detail geometry of the various features that comprise it. The goal of casting design is twofold: (1) satisfy the functionality and service requirements of the application; and (2) specify a casting configuration and detail design that results in low cost, high inherent quality, and short lead time. Both of these goals must be achieved if the casting is to be successful. Key design consideration include:

- What casting design will maximize economy and ease of the chosen process?
- What casting design will maximize the strength of the casting?
- What casting design will minimize the weight of the casting?
- What casting design will minimize stress in the mold and avoid tearing and cracking during solidification?
- What casting design will best facilitate proper positioning of gates, risers, and chills to insure soundness of the casting?
- What casting design will best establish and control solidification?
- What casting design will best facilitate secondary processing such as heat treatment and machining?

Specifying the best overall configuration, geometrical layout of features, and detail dimensions and tolerances that balances these considerations is the essence of casting design. This section presents a variety of guidelines for casting design that are based on a broad synthesis of the many aspects of casting design discussed in the previous sections. The guidelines are generally applicable to all alloys and casting processes. However, when applying the guidelines, the designer must consider particular geometry/alloy/process interactions that may be unique to a given alloy and process combination. In some instances, these interactions may dictate geometry decisions that differ appreciably from the guidelines presented here.

Use a Concurrent Engineering Approach. Finding the most appropriate balance between the many considerations that influence casting design requires close collaboration between the design engineer and the foundry. It is therefore strongly recommended that, as a minimum, the designer (or buyer) consult with the foundry and tooling engineer before developing the final design. Preferably, a concurrent engineering approach such as that discussed in Sec. 11 is recommended.

Design for Strength and Stiffness. The strength and stiffness of the casting will be maximized by locating material where it is needed while avoiding unnecessary bulk and weight (Figs. 8 and 9). For example, if the casting is subjected to bending, then ideally the section modulus ($z = I/c$) at each section should be adjusted so that deflection is within specification and the maximum stress is equal to the allowable design strength of the chosen alloy. In general, configuration designs that utilize continuously varying section geometry to take full advantage of material properties are preferred since these configurations tend to minimize weight and also fully leverage the advantages of the casting process. This practice, which is often referred

Fig. 8 Weight comparison for beam cross sections having equal deflections. Note that W equals the weight of the beam having the 1×1 cross section and that the length and loading for each beam is identical

Fig. 9 The area moment of inertia (I) of the four beam cross sections shown illustrate the importance of metal distribution on the load carrying capacity of a beam. All four sections have the same area and weight, and all except the round shape have the same width and height. Also, $I_{xx} = I_{yy}$ for all four cross sections. Note that the cross and round sections have only about 50% of the rigidity of the I-beam and the heavy concentration of metal in the central area of these sections makes them more susceptible to shrinkage cavities

to as *shape optimization*, has been greatly facilitated by the development of powerful engineering workstations and solid modeling software that significantly enhances the engineer's ability to visualize complex three-dimensional geometry and to analyze stress levels and deflections of complex three-dimensional shapes. As has been discussed previously, an assortment of defects including variation in mechanical properties may occur as the result of hard to control factors that influence the casting process. The use of experimental methods (e.g. photo-elastic, brittle coatings, etc.) to help verify the design of more complexly shaped castings, especially those that involve load or deflection critical applications is generally recommended.

Minimize Casting Weight. Minimizing the weight of the casting minimizes material cost. It also helps to reduce the cost of material handling during production of the casting as well as during subsequent machining and assembly. In addition, lighter weight castings reduce energy costs throughout their life cycle. Weight of the casting can be reduced by (1) designing the casting for strength and deflection as discussed previously; and (2) by utilizing a minimum uniform wall thickness everywhere in the casting. Typical minimum wall thickness for investment casting, premium sand casting, and conventional sand casting are 1.5 ± 0.15 mm, 1.8 ± 0.4 mm, and 2.5 ± 0.5 mm, respectively.^[6] There are a variety of design approaches that facilitate the use of thinner walls. For example, the use of ribs enables the foundry to produce thinner walls (Fig. 10). Similarly, increasing section depth allows the use of thinner walls (Fig. 8).

Use Casting Process Simulation. In *casting process simulation*, comprehensive modeling of the intended production process is performed in order to determine the size and shape of sprues, runners, gates, and risers. A variety of software for performing this type of simulation is available. In addition, methodologies have been developed to understand and predict the size and location of process related defects (microporosity, etc.). Using these methodologies, the rigging system design can be varied in the foundry system simulation to evaluate how defect size and location are to be controlled and/or eliminated. Using computer simulation early in the design process can greatly reduce the amount of "guess work" involved in specifying cost effective and functionally acceptable

Fig. 10 Depending on design considerations, ribs may be cast in many different configurations as illustrated by the two examples shown here^[6]

casting geometry. Computer based casting process simulation offers two important advantages: (1) design iterations and "what-if" analysis are much easier to perform; and (2) the "physics" engine under lying the simulation software provides a consistent and predictable science base for casting design. This allows the casting geometry and rigging system to be specified and optimized as a coordinated system. Most importantly, it allows evaluation of the overall design before tools are cut and the design is irreversibly committed to hardware. When used properly, the result is a substantial reduction in design time and tooling iterations. It is extremely important to note however, that the use of casting process simulation software is not, in itself, a viable substitute for early input of experienced tooling and foundry engineers. Rather, it is a very powerful tool that helps leverage and assist the concurrent engineering approach.

Design for Casting Soundness. Hot spots, which cause shrinkage defects and hot tears, result when the casting geometry interacts in undesirable ways with the solidification process. To avoid hot spots, the geometrical layout of the casting must insure an ample supply of molten metal to feed shrinkage throughout the solidification of the casting. The following guidelines represent preferred practice for most casting design situations. However, it is extremely important that the designer also considers specific interactions and implications that are unique to the particular combination of alloy and casting process being used.

1. **Design for uniform wall thickness.** Shrinkage cavities will form in heavy sections that are fed by light sections because the light section will freeze and cut off the supply of molten metal. When heavy sections cannot be avoided, then risers or other costly foundry remedies such as chilling must often be used. A far preferable approach is to avoid heavy sections by designing the casting to have a uniform wall thickness (Fig. 11). In addition to helping to prevent hot spots, uniform wall thickness also helps prevent undesirable residual stress and warping of the casting. Most importantly, uniform wall design tends to minimize casting weight.
2. **Taper or flare sections toward risers.** Tapering the geometry toward the source of molten metal helps direct and control the solidification front so that it

Fig. 11 Component redesigned to reduce section thickness and provide a more uniform wall thickness, eliminating hot spots and shrinkage effects, reducing component weight, and reducing production cycle time (thin sections cool faster)

progresses from the cooler region into the hotter region thereby insuring an ample supply of molten metal at all times. This practice is of particular importance for alloys that tend to solidify directionally.

3. **Avoid isolated hot spots and sharp internal corners.** As a general principle, the corners of all intersections and junctions should have fillet radii. The size of the fillet radii used must often strike a balance between stress concentration and the possibility of a hot spot (Fig. 12). If the corner is too sharp (i.e. the fillet radius is too small), the flow of molten metal during filling will be inhibited and high stress concentration due to the small fillet radius can cause cracking during cooling or use of the casting. Conversely, if the fillet radius is made too large, isolated hot spots can occur because the metal mass at the intersection will be larger than the features that are joined. The casting designer should therefore specify corner radii that are neither too large or too small to insure that both of these undesirable effects are avoided (Figs. 13 and 14). Often the best choice will depend on the particular alloy. For example, alloys that exhibit little solidification shrinkage are typically not sensitive to junction design.^[4]

Design to Avoid Hot Tears and Distortion. As the casting solidifies and cools, it shrinks. If the mold walls and/or cores inhibit or constrain this shrinkage, internal stress will develop (Fig. 15). This can result in hot tearing or cracking if the stress exceeds the strength of the alloy or the stress may be “frozen in” as residual stress causing distortion and warpage of the casting when it is removed from the mold and/or when it is machined. Similar effects will occur if different sections of the casting cool at different rates or if the distribution of metal is asymmetric (Fig. 16). The best way to avoid hot tears and distortion is to avoid asymmetrical distributions of metal and to use a uniform wall thickness everywhere. When this is not possible, transitions to different section thickness should be carefully designed so that the degree of constraint imposed on the solidifying casting is minimized (Fig. 17).

Design for Metal Flow. Misruns and cold shuts occur when the molten metal solidifies prematurely in cross-sections that are too long and narrow or that are too thin. Minimum section thickness for castings are a function of the alloy composition, size, and configuration of the part. A casting is designed for metal flow by properly considering

Fig. 12 Avoid both too small and too large radii at the intersection of sections

Fig. 13 Detail junction design. Recommended values for r , R , H , and X typically fall in the following ranges: $0.5t \leq r \leq t$, $0.3T \leq R \leq 0.5(t + T)$, $0.3T \leq H \leq 0.5(t + T)$, and $3T \leq X \leq 4T$. The actual best values to use ultimately depend on requirements of the application and on the particular alloy and casting process being used

Fig. 14 Avoid narrow peninsulas of mold material and sharp internal corners to avoid hot tears and cracking

the fluid life of the alloy. Alloys having poor or fair fluid life require thicker sections than those having good to excellent fluid life.

Design for Low Foundry Tooling Cost. The number of foundry tools and the number of operations required to make each piece of foundry tooling are directly determined by the casting design. Similarly, the number of operations

Fig. 15 Staggered ribs reduce distortion caused by thermal contraction, reduce metal mass in local areas, and minimize the possibility of hot spots

Fig. 16 Avoid asymmetrical distribution of metal since this can cause distortion, especially in long castings

required to make the molds and cores and assemble them for casting is determined by the casting design (Fig. 18). Therefore, every opportunity should be taken to minimize casting complexity and promote ease of fabrication while the design is in the very early stages of development, when conceptual maneuverability is wide and the design is easily changed.

Design for Heat Treatment. Guidelines for achieving a heat-treatment friendly casting design include the following:

- Provide flat surfaces of ample size to support the casting in the furnace. Avoid large thin walls and irregular contours that have no flat surfaces. Castings that are difficult to support will distort during the high temperature treatment.
- Avoid large areas of relatively thin and unsupported walls, as these are likely to sag out of shape or position.
- Avoid relatively long and thin shapes, especially those with unequal walls and unsymmetrical metal distribution (Fig. 16). Such shapes will require supporting racks to prevent bending and can also warp during

Fig. 17 If a heavy section is unavoidable, transition to thinner sections should be blended over a significant length, preferably by using a smooth parabolic arc. Recommended values for R and X are: $0.3T \leq R \leq 0.5(t + T)$ and $3T \leq X \leq 4T$. The designer should consider the characteristics of the alloy and casting process as well as the requirements of the application to select the best value

Fig. 18 External and internal undercuts can be readily cast, but such features require sand cores, loose pieces, collapsible cores, moving cores, or complex parting planes. Using any of these increases tooling and production costs. Whenever possible, no cores or simple cores with core pull direction normal to the parting plane is preferred

quenching. Although straightening operations may correct this, straightening is costly and may cause small hard-to-find cracks.

- Avoid sudden and drastic variations in wall thickness. Such features can introduce severe residual stress as well as wide variation in mechanical properties (Fig. 17).
- Avoid casting configurations that might prevent almost simultaneous contact of the quenching medium with all surfaces of the casting. A rapid and uniform quench is necessary to insure good and uniform mechanical properties and to reduce residual stress.
- Avoid large, hard to handle shapes that are not easily transferred rapidly and safely to the quenching tank. Quenching needs to take place within 30 sec after the casting is removed from the furnace to achieve optimum results.

When these guidelines cannot be followed, the designer is advised to consider the selection of an alloy that is suitable for lower temperature aging-only heat treatment or an alloy that is self-aging. This avoids the limitations associated with the T4 cycle as well as the expense of this cycle.

Design for Machining. Suggested guidelines for ease of machining include the following:^[7]

- Reduce the volume of material to be removed.
 - Minimize the size of surfaces to be machined.
 - When possible, minimize machining allowances. Small surface size and less accuracy require less machining allowance.
- When possible, specify alloys and heat treatments that result in good machinability.
- Avoid tight tolerances.
- Avoid excessively smooth surfaces.
- Drive toward a minimum number of machining setups and operations.
 - Design the casting so that all machining is performed on orthogonal and/or parallel surfaces (e.g. design so that all drilled holes are orthogonal to a machined surface).
 - Design so that all processing in one direction can be completed before moving to the next.
 - Minimize the number of machining directions (Fig. 19(a)).
- Insure access to surfaces that are to be machined.
- Provide clearance for tools (Fig. 19(b)).
- Specify features such as fillet radii that allow shorter tool path lengths (Fig. 19(c)).
- Use standardized features; avoid non-standard features whenever possible. For example, use only one standard fillet radius and one standard thread size.
- Avoid sharp angles, edges, and corners as these features typically cool faster resulting in harder to machine material properties.

Fig. 19 Approaches for simplifying the machining of a casting^[7]

CONCURRENT ENGINEERING

Casting design is the first step in the multi-step process that is required to introduce a new casting into production (Fig. 20). All of the steps that follow the initial casting design are dependent on and often constrained by the casting geometry that is specified in this first, and most important step. Ideally, the casting geometry should afford the foundry and toolmaker the greatest possible latitude to seek rigging system and tooling approaches that maximize the soundness and quality of the casting for the least possible cost and in the shortest possible lead time. It is therefore essential that the requirements of the “downstream” steps be properly considered in the casting design. *Concurrent engineering* is the term used to describe design processes in which all “stakeholders” including foundry, tooling, and secondary processing interests are represented from the beginning.

The concurrent engineering approach is needed in casting design because the process of designing a casting is iterative. The problem of design is typically formulated in terms of functional requirements and constraints that must be satisfied. Functional requirements relate to the functions the part must provide while constraints relate to the form (shape, size, surface finish, precision, etc.) and processing (parting line, draft, section thickness, etc.) requirements that constrain the geometry that can be selected. Based on the problem formulation, an initial design is created. This design is then evaluated and modified *iteratively* until an acceptable design is achieved. Typically, the redesign is guided by the design information, insight, and understanding that is developed in the evaluation step. To be acceptable, the design must satisfy all functional requirements and constraints.

When the casting development process is examined, it is seen that the iterative process is essentially repeated at least two and perhaps several times (Fig. 20). First the design engineer goes through the iterative design process to specify the casting geometry. This geometry is then passed on to the casting engineer who repeats the iterative design process to specify the rigging system and apply pattern maker shrink to the casting dimensions. Problems discovered during rigging system design can generate additional iterations if casting geometry changes are required. Additional iterations to the casting geometry and rigging system design may also be required during tool fabrication and preparation for production of the first article. Finally, iterative changes to the tooling and perhaps the casting and rigging system geometry may be necessary to “tweak” the design to meet production requirements.

Excessive design iterations can adversely impact the casting design in two important ways. First, design iterations significantly increase design cost and time. Second, design iterations, especially those performed late in the process, can lead to suboptimal design. The result is a casting that falls short of cost, weight, and performance targets.

Fig. 20 Casting development process

Improvement Strategies

Concurrent engineering seeks to improve the casting design process by implementing the following strategies. The goal of these strategies is to shorten the design cycle and help ensure that the best possible casting design is created.

1. Develop a thorough understanding of all customer needs including downstream processing constraints before beginning the design.
2. Design the casting geometry and casting process as a coordinated system by integrating casting geometry and rigging system design into one concurrent process. Consider geometry, material, and process interactions and design related cost drivers from the beginning as part of the process.
3. Focus on creating an acceptable initial design. By spending the time “up-front” to create the best possible initial design, a large number of lengthy analyze-redesign iterations are avoided. The evaluation phase should confirm the design rather than create it.

Structured Team Approach

One way to implement concurrent engineering in casting design is to use a structured team approach. In a *structured team approach*, the casting design is performed using a multi-disciplinary team and a structured design methodology. The goal is to have all required product and process knowledge available when the key early design decisions are being made. In a structured design methodology, the overall problem of design is broken down into a series of sequential, easier to perform steps that proceed from the general to the specific. Excessive iteration and long design times are avoided by performing each step in a thorough and disciplined manner. In general, each step in the process can be further subdivided into steps to create a hierarchy of structured methodologies.

To illustrate the structured team approach, consider the simple methodology shown schematically in Fig. 21. This approach, which is derived from the general discussion of structured team approach presented in,^[7] recognizes that not all members of the team can be available for designing the casting on a continuous basis. Team meetings are therefore scheduled at which all salient aspects of the design are reviewed and discussed. The outcome of each meeting is a set of action steps to be implemented by individual team

Fig. 21 Simple structured team approach^[7]

members. In this way, all team members are kept informed and participate in the design decision making process. At the same time, the actual detail work of creating the design is delegated to specific team members according to the skills and knowledge required. Each step of the methodology is briefly discussed as follows:

Step 1: Form Team. This is the pivotal first step in the methodology. A typical team might include a design engineer, a casting engineer, a tooling design engineer, and perhaps one or more specialists who are familiar with casting process simulation software, finite element analysis, fracture mechanics, non-destructive evaluation (NDE) techniques, and so forth. In addition, it is important that the end customer, the foundry that is to make the casting, and others concerned with secondary processing that is to be “farmed out” be properly represented on the team. This not only helps ensure that all customer and processing needs are appropriately considered, it also makes it possible to rapidly negotiate changes to the design specification when necessary, and to quickly assess cost consequences of design decisions.

Meeting 1: Clarify the Design Problem. Clarifying the problem consists of developing a general understanding of the cost, performance, and manufacturing goals and constraints of the design. A typical agenda for this meeting might include the following:

1. Review product background.
2. Customer requirements and design objectives.
3. Expected annual production volumes and target costs.
4. Geometry concepts and alternatives.
5. Material and processing options.
6. Foundry and secondary processing locations.
7. Potential geometry/material/process interactions.
8. Develop a preliminary configuration design.
9. Make assignments to team members to create the initial design.

Step 2: Create the Initial Design. The initial design establishes the detail layout of the casting geometry. It includes the configuration and parametric design of the part together with the rigging design required to fill the mold cavity and feed the solidifying casting. Configuration design involves the determination of what features such as walls, holes, ribs, etc. will be present and how these features will be connected to provide the desired form, fit, function, and manufacturability (e.g. parting line, coring, and draft for low tooling cost, short cycle time, and minimal trimming and secondary processing). Parametric design involves the determination of dimensions, tolerances, and exact material specifications needed to meet durability, stiffness, and/or natural frequency targets. As discussed previously, rigging design involves the location and sizing of the sprues, runners, gates, and risers.

Meeting 2: Refine and Approve the Initial Design. The goal of this meeting is to react as a team to the initial design and to make any adjustments or modifications deemed necessary by general consensus of the team. This is the time when all design and processing issues should be discussed and resolved. If there are significant impediments to the design as proposed, these should be resolved before proceeding to Step 3.

Step 3: Refine and Optimize the Design. Once the team is confident that the initial casting geometry and rigging design is the best solution possible, the effort required to optimize details of the casting geometry and rigging system by computer analysis can be justified. The goal of this step is therefore to computer model the design and iteratively improve it until all aspects have been appropriately optimized. The amount of effort expended on this step will depend on how important it is to optimize the casting. For example, if weight and/or material cost is critical, extensive effort to minimize the amount of material used can be justified. Similarly, if safety is an important issue, comprehensive analysis to ensure acceptable fatigue life and reliable detection of flaws can be justified. The key to this step is to start with a casting geometry that is close to the optimum. This will minimize the time, analysis effort, and number of iterations required to converge to the optimum design.

Meeting 3: Approve the Final Design. The result of Step 3 will be a fully specified casting design including the detailed casting geometry, parting plane, draft, coring, riser locations and sizes, and rigging system design. In addition, the finished part design including machining, heat treating, and so forth will be fully specified. The purpose of Meeting 3 is to formally review the finished design as a team and approve the design for release to manufacturing. When the structured team approach is performed properly, the final design will almost always be approved. However, if the team decides that the design is not ready to be released, then appropriate action plans for correcting design deficiencies must be developed and implemented. One or more follow-on meetings may then be required before the design is released.

Barriers

Although simple in concept, concurrent engineering can be difficult to implement because of long standing casting procurement practices employed by many firms. These practices, such as the requirement that a competitive bidding process be used to select the foundry, often present a major barrier to an effective concurrent engineering casting design process because they force separation between casting design and the foundry. Finding creative ways to eliminate or overcome this unnatural separation is essential for the effective design of castings that meet cost, quality, and performance targets and that also transition into production in a timely and cost-efficient manner.

Abstract

An overview of the effect of elemental composition on resulting properties of castings will be provided in this article. Additional topical coverage includes: molten metal processes, solidification, casting processes, die casting, heat treating, computational modeling, and microstructural evolution and control.

Keywords: Casting processes; Die casting; Heat treating; Microstructure; Modeling.

INTRODUCTION

Metal casting is reported to be a prehistoric event that appears, on the archeological records, after evidence of earlier metalworking. It is assumed that the earliest castings were made from native metals and alloys at least 10,000 years ago. Among the first metals to be cast by humankind are copper, gold, tin, lead and silver, whereas aluminum is one of the newest.

Aluminum is affected by several elements; some of them will improve its properties, allowing in some cases for heat treating, but others will be detrimental. A comprehensive account of the different effects can be found elsewhere,^[1] and here only a brief summary will be provided.

- Antimony contributes to the modification of the eutectic aluminum-silicon aggregate into lamellar form; the degree of modification depends on the absence of phosphorus and cooling rate. Antimony can react with strontium or calcium to form coarse intermetallics which affect both fluidity and the eutectic structure. Another detrimental effect of antimony is related to its potential toxicity.
- Beryllium addition of a few parts per million are effective to reduce oxidation losses. This element affects the morphology of iron-containing particles, with the corresponding improvement in strength or ductility. Beryllium oxide is very toxic and its compounds are listed as carcinogens, therefore special precautions have to be taken during melting and handling while liquid and its dross.
- Boron combines with other metals to form borides, such as AlB_2 and TiB_2 . Titanium boride forms stable nucleation sites for active grain refining particles in molten aluminum.

- Calcium is a weak eutectic modifier agent, but it is scarcely used due to the increase of hydrogen solubility which is often responsible for casting porosity.
- Chromium additions are made in low concentrations to suppress grain growth in alloys susceptible to this phenomenon. The compound $CrAl_7$ is accounted for grain growth suppression due to its low solubility. Chromium improves corrosion resistance in some alloys.
- Copper is employed to increase strength and hardness in heat treatable alloys, this element exhibits detrimental effects like reduction in general corrosion resistance, to hot tearing and in castability.
- Iron improves hot tear resistance and reduces the tendency for die sticking or soldering in die casting. Increment in iron content reduces, however, ductility and machinability. Iron forms a series of insoluble compounds which affect the properties of a casting.
- Magnesium contributes to the increase in hardness and strength in aluminum-silicon alloys since Mg_2Si solubility is temperature dependent.
- Manganese is considered to be an impurity in castings and is controlled to a minimum level. It combines with iron to form insoluble phases.
- Nickel is used in combination with copper to enhance high temperature properties.
- Phosphorus is considered to be an impurity in castings due to the reduction of effectiveness of commonly employed modifiers, sodium and strontium, although it contributes to the reduction of primary silicon particles in hypoeutectic Al-Si alloys.
- Silicon increases casting characteristics of aluminum, it improves fluidity, hot tear resistance and feeding behavior. The optimum amount of silicon depends on the casting process. For slow cooling rate processes

(sand or investment), the range is 5–7%, for permanent mold 7–9% and 8–12% for die casting.

- Sodium modifies the aluminum-silicon eutectic. It readily reacts with phosphorus reducing both the modification effectiveness and the size of primary silicon phases.
- Strontium is used to modify the aluminum-silicon eutectic at very low addition levels (0.008–0.04%). Higher additions are associated with the increase in porosity.
- Tin is effective in reducing friction and it is employed in bearing applications.
- Titanium is extensively used to refine grain size in aluminum castings. It is commonly employed in combination with boron.
- Zinc is added to aluminum in some alloys due to the excellent response to age hardening.

The variety of effects from different elements arises the need for grouping the different alloys. The Aluminum Association of America has designed a series of families of alloys:

- 1xx.x: Unalloyed compositions.
- 2xx.x: Alloys containing copper as their major alloying element.
- 3xx.x: Aluminum-silicon alloys also containing magnesium or copper.
- 4xx.x: Binary aluminum-silicon alloys.
- 5xx.x: Alloys containing magnesium as the major alloying element.
- 6xx.x: Unused.
- 7xx.x: Aluminum alloys containing zinc as the major alloying elements. It is common to find additions of copper, magnesium, chromium or manganese.
- 8xx.x: Aluminum alloys containing tin as major alloying element.
- 9xx.x: Unused.

Of these series, the most commonly employed is the 3xx.x due to the increase in fluidity encountered by the addition of silicon, and to the age hardening response achieved by addition of copper or magnesium. Cast pieces made from series 2xx.x 3xx.x and 7xx.x can be subjected to heat treatment, whereas the others are not.

MOLTEN METAL PROCESSES

Melting of commercial casting aluminum alloys require a series of steps other than melting and alloying. Molten aluminum alloys have to be protected from oxidation by fluxing and pumping, whereas their microstructure and mechanical properties, can be improved by degassing, grain refining, modification and filtration.^[2,3] Some of these processes will be described in this section, leaving

aspects related to grain refining and modification to the following section, where solidification phenomena are presented.

Fluxing

The term fluxing is used in the industrial practice to refer to the additives and techniques employed to purify, cover, clean, protect, deoxidize and refine a molten metal bath. Oxides and other nonmetallic inclusions can be formed in molten aluminum and they might be able to incorporate and downgrade an otherwise healthy casting. These inclusions can be originated from dirty tools, sand and other molding debris, sludge, lubricant and liquid residues, as well as from oxidation of alloying elements of the base metal.

Fluxing the melt facilitates the separation and agglomeration of undesirable particles from the liquid alloy. This process is temperature dependent, and it should be carried out at temperatures high enough to enhance chemical reactions and to facilitate physical separation of the molten alloy and the slag.

The compounds employed in fluxes should be able to comply to the following characteristics:

- They should form low-melting high-fluidity mixtures at the working temperature.
- They should decompose to generate anions capable to react with impurities in the melt, which will separate from it due to differences in density.
- They should be able to agglomerate the undesirable products and facilitate their removal by mechanical or any other physical means.

Table 1^[4] lists some of the compounds available for fluxing aluminum alloys.

Different types of fluxes are employed in the foundry industry depending on their function. Among them the principal are: cover, cleaning, drossing and refining fluxes.

- Cover fluxes are designed to be used in small furnaces to provide a physical barrier to oxidation of the melt and clean scrap, foundry returns or ingots being charged. These fluxes should be able to melt on the molten surface and wet the charge. Some fluorides and chlorides are designed to be used in furnaces and small crucibles. These fluxes are cost effective in oxidizing conditions, particularly in alloys with high levels of Mg.
- Cleaning fluxes are higher in chloride salts (70–75%) to facilitate wetting of oxide inclusions for easier separation from the melt and keep the walls and crucibles free of build-up.
- Drossing fluxes are designed to promote separation of aluminum oxide (Al_2O_3) from the dross layer formed on top of the surface of the molten alloy, since sludge, liquid and molten metal are usually mixed in this layer.

Table 1 Characteristics of compounds used as fluxes for aluminum alloys^[4]

Compound	Chemical formula	Density (g/m ³)		Melting point (C)	Boiling point (C)
		Solid	Liquid		
Aluminum chloride	AlCl ₃	2.440	1.31	190	182.7*
Aluminum fluoride	AlF ₃	3.070	—	1040	—
Borax	Na ₂ B ₄ O ₇	2.367	—	741	1575
Calcium chloride	CaCl ₂	2.412	2.06	772	1600
Calcium fluoride	CaF ₂	3.180	—	1360	—
Carnallite	MgCl ₂ KCl	1.600	1.50	487	—
Zinc chloride	ZnCl ₂	2.910	—	262	732
Zinc fluoride	ZnF ₂	4.840	—	872	—
Cryolite	3NaFAIF ₃	2.970	—	1000	—
Lithium chloride	LiCl	2.086	1.50	613	1353
Lithium fluoride	LiF	2.295	1.80	870	1676
Magnesium chloride	MgCl ₂	2.325	—	712	1412

Calcium fluoride	CaF	2.790	1.91	980	1700

*Sublimes at indicated temperature.

These fluxes are designed to react with the alumina in the dross and recover the metal.^[5] They contain compounds, usually fluorides, capable to react exothermally, thus increasing in a local manner temperature and fluidity of the flux. The salts wet and dissolve thin oxide films according to the reaction:

- These fluoride salts can only dissolve the very thin coat of alumina formed on top of the melt, massive Al₂O₃ particles can only be reduced by electrolytic means.
- Refining fluxes contain compounds that break down at the working temperature and are thermodynamically favorable to react with undesirable metallic elements in the base metal. Chlorine in fluxes reacts with alkaline metals to form compounds that can be removed by skimming.

Degassing

Aluminum and its alloys are very susceptible to hydrogen absorption in the molten state due to its high temperature solubility,^[6,7] Fig. 1, and the affinity of aluminum for oxygen. The principal source for hydrogen comes from humidity of the atmosphere in contact with the liquid metal, which reacts with aluminum:

various aluminum alloys have different sensitivities to hydrogen absorption and ensuing gas porosity if removal is not accomplished. Increment of copper and silicon reduces hydrogen solubility, whereas magnesium increases it,^[6] Table 2. Since the solubility of hydrogen is significantly higher in the liquid state as compared with the solid, there will be enrichment in the liquid during solidification. If it

Fig. 1 Solubility of hydrogen in aluminum at one atmosphere^[2,6,7]

Table 2 Solubility of hydrogen in aluminum and its alloys at 750°C^[6]

Alloy	Hydrogen solubility (ppm)
Pure aluminum	1.20
Al-7Si-0.3 Mg	0.81
Al-4.5 Cu	0.88
Al-6Si-3.5 Cu	0.67
Al-4Mg-2Si	1.15

is assumed no solid diffusion and complete liquid diffusion occurs during casting, at the end of solidification there will be a large increase in hydrogen concentration in the piece. Therefore, even when the hydrogen content is below the solubility for the bulk liquid during solidification, concentration in the liquid will increase, and the solubility limit might be exceeded, resulting in a porous part.

Various thermodynamic and kinetic factors control hydrogen removal from molten aluminum. Gas removal is easier at lower temperatures and higher concentrations. Hydrogen is removed by:^[8]

- Hydrogen transport in the melt to the vicinity of an inert gas bubble by convection and diffusion.
- Diffusivity transport through the thin boundary layer surrounding the bubble.
- Chemical adsorption onto and subsequent desorption from the bubble surface.
- Diffusion of hydrogen as a gas inside the bubble.
- Escape of hydrogen from the melt surface or at the refractory walls.

Consequently, hydrogen removal will depend on mass transfer coefficients. It was found that purging efficiency depends on the bubble size,^[9] Fig. 2. The use of porous plugs helps improve the rate by providing small bubbles, but they generally coalesce in the bath, reducing the

**Fig. 2** Hydrogen removal as a function of bubble size at two purging flows^[9]

beneficial effect. The use of an impeller with a porous plug improves the rate further by dispersing the bubbles.

It has been found that the addition of chlorine or freon^[10,11] improves the rate in some cases. It is thought that the removal rate is not only due to the increase of the mass transfer coefficient, but also to combination of the halogen with hydrogen:

which is thermodynamically favorable in some circumstances.

When the hydrogen in molten aluminum cannot be thoroughly expelled from the casting product as it solidifies, porosity defects will result. Porosity can be very fine, widely dispersed, or localized in those areas of the casting that are the last to solidify if the entrapped gas concentration is relatively low. Hydrogen microporosity may not be harmful except when pressure tightness is sought after. On the other hand, some gas porosity defects can be fairly large and they might appear as cracks or blowholes.

True gas porosity and shrinkage porosity should be differentiated. The former one is due to the presence of trapped gas and they appear as round holes upon metallographic examination. The latter is due to inadequate feeding during solidification and it is more irregular in shape than gas porosity.^[12] Porosity defects result in the reduction of mechanical properties in aluminum alloys,^[13] Fig. 3.

Melt Refining

Some impurities present in aluminum can be eliminated in the molten bath; among them are the alkali metals. Of these metals, lithium, sodium and calcium are impurities from primary aluminum production that have to be removed to assure casting integrity. In some cases lithium can be associated with melting aeronautical scrap. Magnesium is another metal that can be eliminated in the melt

**Fig. 3** Tensile properties as a function of gas content in an aluminum alloy A356^[13]

and it is normally introduced in the scrap, since several commercial alloys contain magnesium, and they constitute a significant proportion of the scrap market available for recycling.

Removal of these impurities can be readily done in the molten alloy by introduction of chlorine or fluorine, as their reactions with these particular elements is more thermodynamically favorable than that with aluminum,^[14] Fig. 4. This is done in industry by addition of compounds (like AlF_3) or by bubbling gaseous chlorine.

Pumping and Filtering

Molten metals have traditionally been transferred from the furnace to the mold or casting device in ladles which are filled by gravity. Nowadays it is possible to transfer the molten metal with mechanical pumping systems^[15,16] that offer several advantages over the traditional means.

A pumping system allows for high volumes of metal to be transferred in short periods of times, with the resulting increase of productivity. It is also possible to take advantage of this reduction in transportation and holding times, since the metal can be heated up to lower temperatures, which translates into reductions in costs (energy), and in diminishing the risk for trapping hydrogen.^[6,7] Quality of the cast is also enhanced as the pump drags liquid from the bottom of holding reservoirs, avoiding trapping dross or slag.

Another modern development made to increase quality in foundries is that of filtering, especially with the tendency that aluminum has to oxidize. The filtration process consists in passing the molten metal through a porous device (filter) in which inclusions contained in the flowing metal are trapped or captured. The filter itself should be made of a material which does not react with the alloy, and must resist thermal and mechanical stresses without breaking.

Fig. 4 Thermodynamics of metal chloride formation^[9]

Filtration is carried out by different mechanisms. Large particles (greater than $30\mu m$) are trapped on the surface of the filter, and, as they agglomerate, aid filtering other inclusions during subsequent flow. Smaller particles are trapped as the liquid flows through a very tortuous path within the filter itself. The path provides for the increase in probability for a particle to detach from the liquid and attach to the wall of the filtering medium. Particles brought into contact with the filter will be retained by gravity, friction or by chemical or electrostatic bonds.^[3]

Filtration efficiency is affected by several factors. In general filtration is enhanced when the flow rate is reduced, or when the length (depth) of filtration increases, as the probability for a particle to attach to the filter increases.

SOLIDIFICATION OF ALUMINUM ALLOYS

Is not very common to produce cast pieces from series lxx.x since they are soft and their fluidity is poor.^[2] Addition of other elements, especially silicon, increases the filling capacity of aluminum alloys and allows for the obtention of complex shapes. Solidification proceeds through a series of mechanisms, which can be used to control the properties of the piece.

Nucleation and Growth

Transition from the liquid to solid occurs by nucleation and growth,^[2,17-19] in classical theory nucleation theory^[2,17,19] the radius of an spherical stable embryo (r^*) is given by:

$$r^* = \frac{2\gamma_{sl}T_m}{L\Delta T} \quad (4)$$

where γ_{sl} is the solid-liquid interfacial free energy, L is the latent heat of transformation per unit volume, ΔT is the undercooling and T_m is the melting temperature. The critical energy of activation (ΔG^*) for an embryo of radius r^* is given by:

$$\Delta G^* = \frac{16}{3}\pi \frac{\gamma_{sl}^3 T_m^2}{L^2 \Delta T^2} \quad (5)$$

a comprehensive picture of the variation of the ΔG^* with different parameters is given elsewhere.^[20] Homogeneous nucleation is only possible for high undercooling (on the order of $0.25 T_m$ ^[21]). However, any surface, such as cavities, walls or solid particles, may catalyze nucleation at a much smaller undercooling and with fewer atoms required to form the nucleus, following the phenomenon known as heterogeneous nucleation.

Once the nuclei are stable they will start to grow at a rate controlled by the atomic movility across the solid-liquid

interface, and by mass and heat transfer. Solidification implies that at a given time more atoms move from the liquid side of the interface to the solid one that in the other direction. Growth also implies that the interface keeps moving and increasing in size in such a way that solidification will only proceed if the temperature of the interface is below the melting one (T_m), due to the necessity to compensate the interfacial free energy (γ_{sl}) and the latent heat of solidification (L).

Pure metals solidify as fast as the latent heat of solidification is removed from the interface. Two cases can be considered, one in which the heat is extracted through the solid, Fig. 5(a), and in which the temperature of the liquid is above that of the interface. The advancing interface remains plane and perpendicular to the temperature gradient. If one part of the interface moves ahead of the rest it would enter hotter liquid and will slow down. Fig. 5(b) shows the liquid with an inverted temperature gradient, a condition which is met in a casting when the heat is extracted slowly through the surface of the metal into the mold; solidification begins, after undercooling, at the surface and, since the region of the solid-liquid interface warms up due to the release of the latent heat, this interface advances into colder liquid ahead. Under these conditions if a small part of the interface runs on ahead of the rest, bulging out, this region moves into colder liquid and so runs on ahead still faster. The planar growth is now unstable and spikes will grow out from it into the liquid. Similarly, other arms may branch out sideways from the primary ones forming dendrites. These dendrites grow in preferred crystallographic directions, in cubic metals (like aluminum) they grow in the directions of the cube edges of the crystal cell (100).^[22]

Addition of silicon to aluminum results in solidification of an eutectic aggregate,^[23] Fig. 6. The eutectic structures are characterized by the simultaneous growth of two or more phases from the liquid, it is possible to find different morphologies, they will be lamellar when the volume

Fig. 5 Advance of a solid interface; (a) normal temperature gradient; (b) inverted temperature gradient in the liquid

Fig. 6 Section of the aluminum-silicon equilibrium phase diagram showing typical compositions of some alloys^[24]

fraction of each phase is nearly the same or if the interface of a minor constituent is faceted (when its growth is along well defined crystallographic planes, as in the case of silicon^[24]). The structure will have a fibrous aspect when one phase is present in a small volume fraction.^[25]

Microstructural Control

A series of parameters can be employed to describe the metallurgical microstructure of aluminum castings. Separation between dendritic arms is affected by the solidification or freezing rate, distribution and aspect of the eutectic aggregate, as well as grain size, can be controlled by addition of elements or compounds and by the cooling rate. Size and distribution of intermetallic phases is much more complex, since care has to be taken on impurities content and concentration as well as other solidification conditions.

Dendritic Arm Spacing

Solidification of commercial alloys proceeds by formation of dendrites from the liquid. This is especially the case in hypoeutectic aluminum-silicon alloys, in which the dendrites will be of primary aluminum. Distance or separation between the different dendritic arms is normally measured on the secondary branches, rather than on the primary ones, and, for a given composition, it is controlled exclusively by the solidification rate,^[26-31] Fig. 7. Figure 8 shows the difference in size obtained by cooling an A319 alloy at two different rates. Microstructural examination can be used to obtain information related to the rate or time involved during solidification at different places within a complex cast by reference to data obtained in controlled unidirectionally solidified trials.

Engineering castings can be improved by optimization of the dendritic arm spacing (DAS), since both mechanical,^[26-37] Fig. 9, and physical properties,^[38,39] Fig. 10, are enhanced when this parameter diminishes.

Fig. 7 Secondary dendritic arm spacing (DAS) as a function of solidification rate^[26–31]

Fig. 8 Micrographs of dendrites obtained from samples solidified at low (a); and high (b) rates

Grain Structure

A small equiaxed grain size structure is sought-after in aluminum alloy castings because it improves resistance to hot tearing and mass feeding, at the same time that most mechanical properties and surface finish characteristics are improved. Another advantage of small equiaxed grain structure over large columnar ones is that of homogeneity, which results in less segregation and better response to heat

Fig. 9 Mechanical properties of a C355-T6 alloy as a function of DAS^[35]

Fig. 10 Thermal conductivity in a A319 alloy as a function of DAS^[38]

treatment. A more homogeneous structure has defects, such as porosity and intermetallics more uniformly distributed and therefore less harmful.

Increment in the resistance to hot tearing with reduction in grain size is attributed to decrease in the coherency temperature;^[40] combination of a large volume fraction of eutectic liquid and low coherency temperature in aluminum-silicon alloys results that material containing at least 5% of silicon exhibits a low crack tendency.^[41] Mass feeding and reduced shrinkage porosity are thought to be associated with grain refining, although there is not enough evidence for it.^[42] There is evidence^[43] that in aluminum-silicon alloys as the grain is refined, porosity due to hydrogen is reduced.

Reduction of grain size is achieved by increasing the nucleation efficiency of primary aluminum embryos. This can be done by increasing the cooling rate (which will also help to improve the properties as the DAS is reduced) or by mechanical agitation to detach dendrite arms, but in practice, addition of chemical aggregates is used to provide the necessary nuclei.

In most casting processes the metal solidifies as soon as it touches the walls of the mold, and, due to the high nucleation rate encountered in this region, a layer of small equiaxial grains is formed, Fig. 11. This layer finishes when nucleation is stopped by the increase in temperature produced by the release of the latent heat of solidification (L). Some of the originally equiaxed grains will be able to grow nevertheless, forming a layer of big columnar grains, which contribute in the reduction of mechanical properties in the piece. This columnar region ends when the temperature gradients change and nucleation of new grains takes place. Addition of particles which are able to nucleate with low undercoolings (below 1°C), such as the intermetallics $\text{Al}_{15}(\text{Fe,Mn})_3\text{Si}_2$, can be formed in front of the columnar grains and they will promote formation of new aluminum grains.^[43]

Optimum grain refining can be obtained when a surface is provided at, or just above, the liquidus temperature of the alloy. Such conditions are met with the addition of Al_3Ti particles contained within a master alloy.^[43] Titanium is soluble in liquid aluminum, Fig. 12, and it is required

Fig. 11 Typical grain variation observed in castings

Fig. 12 Section of the aluminum-titanium equilibrium phase diagram

to have at least 0.15% Ti in the alloy to provide for the peritectic reaction and grain refining effectiveness. Industry is moving down to the use of titanium-boron master alloys in which the titanium ranges from 3% to 10% and a Ti:B ratio of 3:50 provides for soluble Al_3Ti and insoluble $(\text{Ti,Al})\text{B}_2$ particles in an aluminum matrix, Fig. 13. Since these master alloys are effective at significant contents in Ti (0.01–0.03% in the cast alloy), it has been suggested that the predominant role in nucleation is taken by the boride particles.^[44]

Modification

The term modification is referred in foundry industry to the morphological changes that take place in the aluminum-silicon eutectic aggregate.^[45] This process can be conducted either in hypo or hypereutectic alloys by addition of different elements or by increasing the solidification rate. Modification changes the sharp needle aspect commonly encountered in untreated alloys, Fig. 14(a), to a fibrous, coral like aspect, Fig. 14(b).

Elements from groups Ia and IIa, as well as some rare earths, can be employed as modifiers, among them sodium and strontium are preferred due to their strong effect at low addition levels. Experimental results show that the degree of modification, for a given alloy, depends on the amount of Sr added, as well as the time evolved between addition and casting. Figure 15 shows such behaviour taking as reference the lowest temperature recorded as the eutectic reaction takes place.^[43]

Crossley and Mondolfo^[46] have proposed a physical model based on the assumption that in unmodified casts silicon grows at a faster rate than aluminum, resulting in sharp acicular particles, addition of sodium or any other modifier agent hinders growth of silicon and promotes that of aluminum as its surface tension is reduced. Shamsuzzoha et al.^[47] proposed that growth of silicon occurs in a ledge-wise manner, in such a way that its {111} planes encroach along the $\langle 112 \rangle$ directions. During slow cooling twinning is frequent, and promotes a small angular distortion along the twinning planes, which is responsible for

Fig. 13 Microstructure of a titanium-boron master alloy

Fig. 14 Typical eutectic structures found in unmodified (a); and modified (b) aluminum-silicon alloys

Fig. 15 Changes in the eutectic temperature as a function of time elapsed since addition of strontium in a A356 alloy^[43]

branching. When the solidification rate is increased, silicon atoms do not have time enough to accommodate in the ledges, promoting a twinning at a higher rate, which implies the increase in distortion and branching. Shu-Zu and Hellawel^[48] have proposed a mechanism based in the enrichment of the modifying atoms at the silicon-liquid interface, in such a way that this absorption will distort the ledges and promote twinning and branching.

Porosity

Porosity in aluminum cast alloys is associated either with the presence of hydrogen (trapped while liquid and expelled as the metal solidifies, due to its drop in solubility, Fig. 1), or to the volumetric contraction occurring as the liquid metal freezes.^[2] Porosity in a casting is irregular due to the combination of the above mentioned factors, however, it is possible to determine the origin of certain pores, based on their distribution and morphological aspects.^[2]

Big macroscopic shrinkage cavities are normally assumed to be due to contraction and are associated to faulty feeding designs, and to the inability to allow liquid metal to flow into already solidified regions. A molten alloy will exhibit three different contraction stages, Fig. 16.^[2] The first one (liquid) does not have a dramatic effect in castings, and it is normally noticed only as a reduction in height of the liquid held in the feeder. Contraction during solidification (second stage) is cause of most problems, and it is due to the change from a random open liquid structure into a more compact solid one. Figure 17 shows how shrinkage cavities can be formed when casting with a faulty feeding design. In this figure, it is assumed that the mobility of the liquid-solid interphase is the same in all directions (t_1), but as time increases (t_2), the faulty design will allow contact between moving interphases, which will result in liquid metal being isolated from the feeder;

Fig. 16 Contraction due to different phenomena^[2]

Fig. 17 Formation of shrinkage cavities due to missdesign of the feeding system

once this liquid solidifies, it will leave behind a series of cavities.

As was mentioned above, the decrease of solubility of hydrogen is thought to be responsible for most small gaseous pores in aluminum castings. A series of models^[49–52] have been developed to explain the formation of these pores based on nucleation and growth mechanisms, models that require different geometrical consideration and the knowledge of difficult to measure parameters like surface tension and super saturation pressure.

Intermetallics

The most common intermetallic phases found in aluminum castings are related to contamination with iron, which has a limited solubility in liquid aluminum.^[23]

Of these intermetallic phases, the β -Al₃FeSi is the most detrimental to mechanical properties,^[53,54] due to its needle shape microstructure, Fig. 18, and its low coherency with the aluminum matrix.^[55] Addition of manganese transform these intermetallics into the less deleterious α -Al₁₅(Fe, Mn)₃Si₂ phase, which due to its aspect, Fig. 19, is commonly referred as Chinese script. A drawback of addition of manganese is the increment in both hardness

Fig. 18 Intermetallic β -Al₃FeSi

Fig. 19 Intermetallic α -Al₁₅(Fe,Mn)₃Si₂

and quantity of intermetallic particles for a given iron content, in such a way that the positive effect of manganese on the modification of the intermetallic morphology to increase the resistance to crack propagation is offset by the increased brittleness and volume of the α particles.^[56]

Intermetallic phases can be formed in aluminum castings at high temperatures, before the aluminum dendrites are formed, concurrent with the solidification of the alloy, or they can form complex eutectic phases which solidify at temperatures as low as 480°C.^[43,53–60] A short summary of the intermetallic phases encountered in Al-Si alloys is presented in Table 3.

Two factors are known to control the morphology and nature of the intermetallics found in cast alloys, and they are the solidification rate and the chemical composition.^[53–60] The solidification rate exerts a direct impact on the kinetics and amount of iron rich phases present in the microstructure. Low cooling rates favor the formation of β needles, which are formed in well defined crystallographic planes, whereas higher rates tends to favor the Chinese script type,^[59] experimental results^[57] show that the transition between β and α phases takes place at slower rates as the amount of iron is reduced. Several authors^[53–60] have shown that the elements that control the transition from β to α depends on the amount of Fe, Mn and Cr, as the former increases β formation will be promoted, while Mn and Cr contribute to the stabilization of α particles.

A series of guidelines can be mentioned to reduce the detrimental effects of iron intermetallics:

- maintain low iron levels.
- maintain a Mn/Fe ratio higher than 0.5.
- increase the rate of solidification.
- reduce the degree of eutectic modification.

Thermal Analysis

When a material undergoes a phase transformation, some of its characteristics (properties and structure) may change discontinuously. Most common transformations, such as boiling, melting and allotropic structural changes, are called first order transformation since the first derivative of the free energy (G) becomes discontinuous at the transformation temperature (T):

$$S = -\frac{dG}{dT} \quad (6)$$

Table 3 Intermetallic phases in Al-Si alloys

Reaction	Phases
Pre-dendritic	Al ₁₅ (Fe,Mn) ₃ Si ₂
Post-dendritic	Al ₁₅ (Fe,Mn) ₃ Si ₂ -Al ₃ FeSi
Eutectic	Al ₃ FeSi-Mg ₂ Si
Post-eutectic	Al ₅ Mg ₈ Cu ₂ Si ₆ -CuAl ₂

where S and T are the entropy and temperature. Since

$$G = H - TS \quad (7)$$

where H is the enthalpy, H must also be discontinuous at T_i in order for both G to be continuous and S discontinuous, Fig. 20.^[61] The discontinuity in H is referred to as the latent heat of transformation, and it is this heat which will be absorbed or released during a transformation that is detected by thermal analysis.

The oldest type of thermal analysis is that of recording the changes in temperature that occurs while heating or cooling a material, which can be obtained by placing a thermocouple within the piece to be studied.^[62] Figure 21 shows the sort of changes which are expected as a pure metal and a couple of alloys during their cooling and heating. The horizontal plateau observed in the pure metal and the eutectic is due to the latent heat of transformation, which has to be provided, when heating, or extracted,

Fig. 20 Temperature dependence of the free energy and enthalpy of a material as it goes through a first or second order phase transformation

Fig. 21 Ideal and observed curves obtained while cooling and heating a pure metal and a couple of alloys

while cooling, in order to achieve full transformation. Both alloys show changes in slope in their cooling and heating curves as they pass through the binary phase region. It is worth noticing that the sharp changes identified as ideal, are not normally observed in most conditions due to factors such as the thermal inertia of the thermocouple, segregation, agitation, etc. This limitation is overcome with the use of the derivative (dT/dt) of the heating or cooling curves, as the points at which the transformations start and end are magnified,^[43,59,62] Fig. 22.

Commercial Al-Si alloys are treated as if they were made only of either primary aluminum or silicon, and the eutectic aggregate, see Fig. 6, although this is far from true. Figure 23 shows the cooling curve recorded during solidification of a type 319 alloy to which titanium and strontium were added, respectively, to refine their grain structure and modify the eutectic aggregate. Four different reactions were detected by plotting dT/dt as a function of temperature, Fig. 24, and they are:

- Peritectic precipitation of Al_3Ti .
- Formation of primary aluminum dendrites.
- Eutectic Al + Si reaction.
- Solidification of complex eutectic of the type $Al_5Mg_8Cu_2Si_6 - CuAl_2$.

CASTING PROCESSES

As was mentioned before, casting has existed since pre-historic times and a wide variety of molding and casting methods and processes have been developed over the time. Figure 25^[63] shows a simplified flow diagram of the basic operations for producing a sand casting. The right hand side of the diagram starts with patternmaking, which refers to all the operations, methods and techniques required to produce a sound quality model and are described elsewhere.^[64]

The molds are made by pressing the sand, bonded either with resin or clay, to the pattern, internal passageways within the casting are formed by the use of cores, which are made of sand and a binder which provide the strength to withstand the flow of molten metal. Casting production begins with melting the metal, see previous sections, which is tapped into a ladle for pouring in the mold cavity, where it is allowed to solidify within the space defined by mold and cores. After it has solidified, the casting is taken out of the mold, the risers and gates are removed, and the

Fig. 25 Simplified flow diagram of the basic operations for producing a sand casting^[63]

piece is heat treated, cleaned and inspected before it is send to the costumer.

Foundry processes can be classified based on whether the molds are permanent or expendable, subclassifications arise from the type of compound used as binder, or from the nature of the pattern (whether or not they are expandable). Table 4^[65] enlists a series of processes commonly encountered in foundries.

Sand Casting

Sand casting is one of the most versatile processes, it provides tremendous freedom of design in terms of size, shape and product quality. Different types of sands, such as silica, zirconia, olivine or chromite, are used in casting, although the most common in aluminum are silica and zircon.

Foundry silica sands are composed almost entirely of quartz, SiO_2 . Some impurities may be present, such as ilmenite FeO-TiC_2 , magnetite, FeO_3O_4 , or the ferrous orthosilicate, $(\text{Mg,Fe}_2)\text{SiO}_4$, known as olivine. Silica sand is used primarily because it is inexpensive and readily available, although the crystallographic reactions that quartz undergoes on heating might produce a series of defects in the casting. The first change in volume takes place at 573°C is due to the displacive transformation of quartz α to quartz β , and involves an expansion of around 1.6%. Quartz β undergoes the reconstructive transformation to tridymite at temperatures above 867°C , which contracts around 0.3%. At temperatures above 1470°C tridymite transforms into cristobalite.^[66]

Zirconia sands are constituted of zirconium silicate (ZrSiO_4), which is highly refractory and exhibits excellent foundry characteristics, such as low thermal expansion, high thermal conductivity and bulk density and low reactivity with molten metal.^[67]

The size, distribution and shape of sand grains are important in controlling the quality of the mold. It should be realized that grain shape contributes to the amount of sand surface area, whereas size distribution controls the permeability of the mold. As the sand surface increases, the amount of bonding material must increase to achieve the desired mechanical properties, and a change in surface area, due to change in sand shape, will result in the change of the amount of binder required. Round grains have a low surface-area-to-volume ratio and are preferred for making cores because they require the least amount of binder. Angular sands have the greatest surface area and require more aggregates. According to the American Foundrymen's Society, approximately 90% of all castings produced in the United States are produced by sand molding.^[68]

Bonded Sand Processes

These processes are characterized by the addition of inorganic materials which bond the sand and include green

Table 4 Classification of foundry processes based on mold type^[65]

Expandable mold processes		
Permanent patterns	Expendable patterns	Permanent mold processes
Clay/water bonds	Foamed patterns	High and low pressure die castings
Heat-cured resin binder	Wax patterns	
Cold box resin binder		Permanent mold
No-bake resin binder		Centrifugal casting
Silicate and phosphate bonds		Squeeze casting
Plaster bonds		
No bond		

sand molding, dry sand molding, skin dried molds, etc. The term green sand refers to the sand molds which have been activated by the addition of water to clay-bonded sand. The clays more commonly employed in aluminum castings are bentonites and fireclays.

Bentonites are forms of an hydrated aluminum silicate (montmorillonite) which is capable of expanding as water is absorbed or contracting as it dries. There are two variants of this clay, in the first one, some aluminum atoms are replaced by sodium, which gives the clay a net negative charge and increases its activity and its ability to absorb water, whereas in the second type some of the aluminum atoms are replaced by calcium. Bentonites confer a high degree of plasticity to the sand and, as they contract when drying, they contribute in reducing the effects caused by the transformations that take place in silica. Fireclay consists essentially of kaolinite, an hydrous aluminum silicate; it is highly refractory but has low plasticity, and it is preferred in large castings.^[67]

When molten metal is poured into a sand mold gases, produced by the thermal decomposition of binders and any other additives employed, result. If the permeability of the mold is not sufficient to allow the escape of these fumes, pressure will increase within the mold, impeding the flow of metal or damaging its walls. But these gases are not always a disadvantage, because the gas pressure prevent metal penetration into the sand, therefore, a balance between mold permeability and the amount of fumes generated must be achieved and maintained. Permeability is controlled by the amount, size and distribution of the voids dispersed among densely packed sand grains, thus sand from a mixture of sieves is commonly recommended.

Another phenomenon which takes place when molten metal is introduced in the mold cavity is that of heat transfer from the liquid to the adjacent sand grains, causing their expansion, and, since it is required that each grain expands freely to avoid damaging the mold wall, these grains should not be densely compacted.^[69]

Resin Binder Processes

Foundries employ a variety of methods and techniques to produce cast metal parts. Molds can be made of sand or be of a permanent metal type, but in either case, when an internal conduct or passageway has to be made a core has to be used. These cores are the most fragile part of the mold assembly and are normally produced by sand bonded with an organic resin. A wide variety of resin binder processes are available, and they can be classified in the following categories:^[70]

- No-bake binder systems.
- Heat-cured binder systems.
- Cold box binder systems.

In the no-bake and cold box processes, the binder is cured at room temperature, whereas in the shell molding and hot box processes, heat contributes to the polymerization reaction.

In all cases the sand is coated with two reactants that form a resin upon the application of heat or a chemical catalyst. The resin converts into a solid plastic that coats the sand so it holds its shape during pouring, an important characteristic of these systems is that the plastic degrades when liquid metal touches the cores, which allows for their rapid disgregation during shaking or further processing.

Unbonded Sand Processes

Casting processes in which the sand does not carry any binding material are alternatives to conventional green sand molding. Of them, the one that is taking more importance in casting aluminum parts is that of lost foam. This process dates from the early '50s and consists in the use of a polystyrene foam pattern imbedded in green sand. The pattern is left within the mold while pouring to be decomposed by the action of the heat from the molten metal, which then replaces the pattern and duplicates its surface.^[71]

Early lost foam was limited to rough castings because the foam material available was coarse, had to be hand fabricated, and the packed sand would not allow the escape of fumes caused by the decomposing foam, which resulted in porous pieces. Quality was enhanced by replacing green sand by unbounded sand, held in place by the pattern, which allowed rapid escape of gases. Another advantage of this method is that of reducing the time cycle of the unbounded sand, as it does not have any binder, it only has to cool down to room temperature before being used in another mold.

There are some disadvantages that affect this method, among them is the distortion to which the foam pattern can be subjected to when the sand is poured into the container or is being packed. Porosity is also a concern, since the foam and the glues employed to hold the full assembly vaporize, some of the fumes might not be able to escape, and they will be incorporated as pores within the piece. Another point of concern is the mechanical properties of the piece, due to the slow cooling caused by the low heat transfer rate between the metal-sand interface, and the thermal inertia resulting from the mass of sand used in molding.

Sand Reclamation

The economics of a foundry rely on sand reclamation to reduce the costs associated with new sand and those related to landfill use, as well as the problems associated with environmental control of undesirable contaminants in discarded sand. Other operational advantages result from sand reclamation, one of them is the ability to select the best sand for the casting process, in addition, the use of reclaimed sand reduces the number of variables that must be controlled, and provides consistency over a period of time.

Sand reclamation starts with the removal of foreign materials, such as metal spills, slag and paper, and the disintegration of lumps of sand. The organic and inorganic binders are removed either by scrubbing or by thermal methods, clay is normally removed as fines. The sand is brought up to specifications by the addition of new sand, clay and any other type of additives. Sand reclamation systems must be selected, taking in mind their cost, specifications of the sand, system capacity, compatibility with the molding and pouring systems and with the type of cores being used.

Permanent Mold Casting

Permanent mold casting is sometimes referred to as gravity die casting, a metal mold is usually made of two or more parts which open and close during operation. Cores can be made of removable metal pieces or, when complexity increases, of sand, in the latter case this process is sometimes referred to as semipermanent mold casting.

This process is suitable for high-volume production of castings with fairly uniform wall thickness and intricate internal coring. The process can be used to produce complex castings, but quantities should be high enough to justify the cost of metallic molds. Compared to sand molding, permanent mold casting permits the production of more uniform parts, with closer dimensional tolerances, superior surface finish and improved mechanical properties. It should be mentioned that this process has a series of limitations, among them are the high tooling costs, which implies a high production volume to make it profitable. Some shapes might not be suitable to cast in a permanent mold due to parting line location, undercuts or difficulties in removing the piece from the mold. Coatings are required to protect the mold from attack by the molten metal.^[72]

A simple permanent mold may consist of only two pieces arranged in a book or similar type of style. The mold cavity when the halves are closed determines the shape of the casting. Metal fills the cavity by means of gates, sprues and runners; risers are added to assure proper filling as the piece solidifies and contracts. The cavity should be vented to allow air to escape. Gating systems for permanent molds are less flexible than those for sand molds, and are nearly always located in parting planes. Gating must supply metal fast enough to fill all sections of the casting with minimal turbulence, otherwise excess of oxide may form endangering the quality of the part. Molds for aluminum alloys are poured in the vertical position to allow for rapid displacement of air (venting). Special care has to be taken when designing the gating system, in most cases, the last metal that enters the cavity is the hottest, and if it remains towards the bottom of the mold, it will interfere with gravity feeding and progressive solidification, and will produce castings with shrinkage porosity.

Coatings are applied to mold surfaces to serve as a barrier between the molten metal and the mold before a skin of solid metal is formed. These coatings perform different functions, among them are: to prevent premature freezing of the metal; to control the rate and direction of solidification; to reduce the thermal shock and fatigue of the mold; and to vent air trapped in the mold cavity. Mold coatings can behave as insulating or lubricating layers, the former ones are based on ceramic formulations, whereas the latter ones usually contain graphite in a suitable carrier.

One of the most important parameters to control is the mold temperature, because if it is too high, excessive flash will develop, castings might be too weak to extract undamaged and their mechanical properties and surface finish may be impaired. When the temperature is too low, cold shuts and misruns will be likely to occur, feeding will be inhibited (which generally results in shrinkage defects), hot tears and sticking of the casting to the mold will be increased. In many operations molds are preheated either by direct flame or by placing hot castings on them. Molds designed for pieces requiring high mechanical

properties are normally cooled by the use of either forced air or water.

Die Casting

All the processes described in the previous sections use gravity as driving force for filling the different types of cavities. When liquid metal is pushed into a cavity, either by a ram, gas or a pump, the process is called die casting, and this can take either at high or low pressure.

Low Pressure Die Casting

In this process liquid metal, held in a pressure tight holding furnace, fills the mold cavity by means of a riser pipe when the top surface of the vessel is pressurized, Fig. 26. After the metal fills the die, it commences to solidify, with the solidification front progressively moving from the extremities of the mold back towards the riser tube, once the front reaches the top of the pipe, the pressure on the vessel is released and the remaining liquid metal falls into the container.

Low pressure die casting is a process very similar to that of permanent mold casting in the sense that the liquid metal enters the die at a relatively low velocity and, ideally, maintains a non-turbulent flow while filling the cavity, but since there is less control of cavity fill and a greater tendency to entrain air in the metal under gravity pouring conditions, the low pressure process should provide higher quality pieces. Another difference between both processes is product yield, the runners and risers in gravity permanent mold casting can amount to 50% of the mass, whereas the yield in low pressure die casting is claimed to be as high as 95%.^[73]

Because the cavity fills at a slow velocity, the dies are normally coated with a thin layer of a ceramic base material to reduce the rate of heat transfer to the metallic mold. This layer also prevents molten metal attack of the die. Complex sand cores can also be used in low pressure die

casting, in contrast with high pressure die casting, where sand cores tend to disintegrate when subjected to the high injection speed.

The everyday competition for lower weights in automotive industry has made some foundries to cast pieces such as road wheels and cylinder heads by low pressure. This process is also being considered for the production of high integrity castings for suspension, steering and braking applications.^[73]

Traditional low pressure die casting uses permanent metallic molds; in some cases, like road wheels production, no sand cores are used, however, when cylinder heads or engine blocks are cast, the sand cores are required. Recent developments in the production of engine blocks has changed the material from which the molds are made, the best known version is that developed by Cosworth,^[74] in which the mold is made from zirconia sand and it is filled by means of an electromagnetic pump, an alternative to this method is the Improved Low-Pressure Process (ILP).^[75] which uses silica sand and fills the mold by the more traditional way of increasing gas pressure, see Fig. 26.

High Pressure Die Casting

High pressure die casting is characterized by the high speed at which the molten metal is injected within the mold cavity. Due to the very high kinetic energy of the liquid metal, no sand cores are normally used, since the impact will disintegrate them. This high kinetic energy is the cause that the machines used to produce die cast parts are rated by the closing pressure that they can exert on the dies, rather than on the capacity or weight of their castings, another limitation of this process is the need to pay for the metallic permanent molds, which translates into high volume and productivity.^[76]

The metal flow in this process is turbulent and much metal will be injected as finely divided droplets which, if the heat transfer rate during solidification is low, may be the cause for porosity. This process is limited to produce small parts, in part due to the need to achieve a high transfer rate and in part due to the high closing pressure that the dies should withstand when big pieces are cast. This process is optimum to produce thin walls (of less than 0.5 mm thick) in high volumes, moreover, several small pieces can be cast together to increase productivity.

The predominant type of die casting for aluminum alloys is that of cold chamber, which consists in a small reservoir (held at a temperature of 160–260°C) in which molten aluminum, taken from a holding furnace, is placed. Once this is done, a ram injects the metal into the cavity. The mold opens once the pieces are solid, the interior of the mold is inspected (in some cases a coating may be employed), and the die closes for the next cycle. Table 5^[73] resumes the differences between low and high pressure die casting of aluminum alloys.

Fig. 26 Schematic diagram of the low pressure process

Table 5 Operating parameters for low and high pressure die casting^[73]

Parameter	Low pressure	High pressure
Cavity fill time	3–30 sec	50–200 msec
Metal pressure	30–100 kPa	10–60 MPa
Gate velocity	0.1–0.6 m/sec	20–60 m/sec
Die temperature	300–450°C	120–260°C
Solidification time	30–300 sec	1–10 sec
Casting-mold heat transfer coefficient	0.2–2 kW/m ² °C	20–90 kW/m ² °C
Cycle time	5–10 min	20–120 sec

HEAT TREATING

The broadest meaning of heat treating comprises all thermal practices intended to modify the metallurgical structure of products in order to control their physical and mechanical characteristics and accomplish specific engineering criteria, but, in aluminum industry, the term heat treating is often used to describe the procedures and practices required to achieve maximum strength or hardness in a suitable alloy. Normal practice involves a sequence of solution heat treating, rapid cooling (quenching) and precipitation hardening (aging). Proper alloying and temper selection allows for the achievement of different features, among them:^[1]

- Improve machinability.
- Achieve the mechanical properties associated with a particular condition.
- Stabilization of mechanical and physical properties.
- Ensure dimensional stability under service conditions.
- Relieve residual stresses induced by different manufacturing operations.

The Aluminum Association has standardized the definitions and nomenclature applicable to thermal practice and maintains a registry of standard practices and designations for industry, of them, the ones applicable to castings are:

- O:** annealed (thermal stress relieved).
- T4:** solution heat treated and quenched.
- T5:** artificially aged.
- T6:** solution heat treated, quenched and artificially aged.
- T7:** solution heat treated, quenched and stabilized (overaged).
- T8:** cold reduced before aging to improve compressive yield strength.

Principles of Heat Treating

Although most metals will alloy with aluminum, few of them have sufficient solid solution to serve as addition. Of the most commonly used elements, only Zn, Mg, Cu

Table 6 Solid solution of selected elements in aluminum^[77]

Element	Temperature(°C)	Maximum (wt%)	Solubility (at%)
Ag	566	55.6	13.8
Cu	548	5.65	2.40
Cr	661	0.77	0.40
Fe	655	0.05	0.025
Mg	450	17.4	18.5
Mn	658	1.82	0.90
Si	577	1.65	1.59
Ti	665	1.30	0.74
Zn	443	70.0	28.8

and Si have significant solubilities, Table 6. The versatility of alloying and heat treatment is manifest in the fact that it is possible to increase the yield strength of high purity aluminum by as much as 40 times.^[76]

The basic requirement for an alloy to be amenable for age-hardening is a decrease in solid solubility with decreasing temperature of one or more of the alloying elements. Such condition is met by different alloying combinations, of them, the most important in castings are Al-Cu, Al-Mg-Si or Al-Zn-Mg, as an example, a section of the Al-Cu phase diagram is shown in Fig. 27.

Age-hardening is produced by the formation of a series of precipitated particles which form from a supersaturated solid solution,^[76,77] Table 7. The complete decomposition of the solution is usually complex and may involve several stages. Early stages of decomposition involve clustering of the alloying elements to form one or two atoms layers of what are called Guinier-Preston (GP) zones. These zones retain the structure of the matrix and are coherent with it. Their formation requires movements of atoms over short distances so they are very finely dispersed in the matrix.

**Fig. 27** Section of the aluminum-copper equilibrium phase diagram

Table 7 Precipitation processes in aluminum alloys^[77,78]

Alloy	Precipitates	Remarks
Al-Cu	GP zones θ''	Probably single layers of copper atoms on $\{100\}\alpha$ Coherent, probably two layers of copper atoms separated by three layers of aluminium atoms. May nucleate at GP zones
	θ' tetragonal Al_2Cu	Semi-coherent plates nucleated at dislocation on $\{100\}\alpha$
Al-Mg-Si	θ body centred tetragonal Al_2Cu	Incoherent equilibrium phase. May nucleate at surface of θ'
	Clusters of Mg and Si atoms. GP zones?	GP zones solvus occurs at temperatures that are normally higher than the aging temperature
	β'' monoclinic	Coherent needles along $\langle 100 \rangle_\alpha$
	β' hexagonal Mg_2Si	Semi-coherent rods. May form from β''
	B' hexagonal Mg_2Si	Semi-coherent laths. Lie along $\langle 100 \rangle_\alpha$. Forms with β' Favoured by high Si: Mg ratios.
Al-Zn-Mg	β face centred cubic Mg_2Si	Platelets on $\{100\}\alpha$ May transform directly from β'
	GP zones	Possibility of two types of zones
	η' hexagonal MgZn_2	May form from GP zones in alloys with Zn: Mg > 3:1
	η hexagonal MgZn_2	Forms from η' . May have one of nine orientation relationships with matrix
	T' hexagonal $\text{Mg}_{32}(\text{Al,Zn})_{49}$	Semi-coherent. May form instead of η in alloys with high Mg: Zn ratios
	T' cubic $\text{Mg}_{32}(\text{Al,Zn})_{49}$	May form from η if aging above 190°C, or from T' in alloys with Mg: Zn ratios

The intermediate precipitates are normally much larger in size than GP zones and they are only partly coherent with the matrix. They have a composition and crystal structure close to that of the equilibrium phase. These intermediate precipitates are, in some alloys, nucleated from, or at the site of the GP zones. Formation of the final equilibrium precipitates involves complete loss of coherency with the parent lattice and, because they tend to be coarsely dispersed, softening of the alloy results.

Heat Treating of Cast Alloys

Heat treating of industrial casting alloys differs from that carried out in wrought alloys due to the presence of complex eutectic phases. For instance, thermal analysis obtained during solidification of a 319 alloy, Figs. 23 and 24, show the presence of a complex $\text{Al}_5\text{Mg}_8\text{Cu}_2\text{Si}_6\text{-CuAl}_2$ eutectic that solidifies below 500°C. If full hardening by aging of this alloy is intended, the material should be heated above 490°C to dissolve the 3.6 wt% Cu it contains, Fig. 27, and at this temperature, any temperature variation within the furnace may endanger the surface quality of the piece, due to melting of this complex eutectic. Unfortunately, decrease in solubilization temperature results in reduction of mechanical properties, Fig. 28.

Another factor that affects heat treating is the time required to put in solution coarse microstructures

resulting from slow solidification rate processes. In general, it is found that the time required to achieve solution is progressively shorter for investment, sand and permanent mold casting, but thin-walled sand castings produced with extensive chills can display finer microstructures than those obtained in heavy-section permanent mold parts.

Rapid cooling or quenching from solution should be taken special care, as it is desirable to keep in solution as much of the alloying elements as possible, but in parts in which transition from thick to thin sections is abrupt

Fig. 28 Stress-strain curves obtained in compression of T4 samples from a 319 alloy solubilized at three different temperatures

distortion will be found,^[78] and the cooling rate should be reduced to avoid it. Most commercial quenching is accomplished in water near the boiling point, but there is a tendency to increase the use of polymers emulsions in room temperature water.^[78,79] Figure 29^[80] can be used to predict whether or not an aluminum casting may be subjected to dangerous high stresses or not as a result of the cooling rate experienced during quenching, and the distance to which heat should diffuse to obtain an uniform quench, i.e. the cooling rate should be reduced with the increase of size and mass of the heat treated pieces.

Experimental trials should be conducted to find a critical cooling rate, above which no increase of hardness is found to occur. Such a case for a 319 alloy is shown in Fig. 30, where the maximum value of hardness in samples aged at 160°C are plotted as a function of the average cooling rate detected in the 400–480°C range, and, as it can be seen, this critical rate results to be around 10°C/sec, which coincides with results obtained in wrought alloys.^[81,82]

Aging of aluminum alloys can be followed by conducting hardness tests in samples left at given temperatures for different times, Fig. 31. Most aluminum alloys age-harden naturally to some extent after quenching. The extent of change is highly alloy dependent, for instance, alloys A356 and C355 age within 48 hr, with insignificant changes thereafter, whereas alloy 520 hardens over a period of years.^[1]

The process of aging can be accelerated by increasing the temperature, but the maximum hardness which can be obtained will be reduced with the increase of temperature, as coarser and more dispersed precipitates will be formed.^[76,77]

The stabilization (T7) treatment can have some advantages over the T6, among them is the reduction in residual

Fig. 29 Threshold for the development of dangerous high stresses in aluminum castings as a function of the cooling rate and the distance for heat diffusion^[80]

Fig. 30 Variation of the T6 hardness achieved in a 319 alloy as a function of the cooling rate averaged in the 400–480°C range

Fig. 31 Aging at 160°C of a 319 alloy solubilized at 480°C for 6 hr

stresses which is achieved as stabilization is conducted at higher temperatures (220–240°C) than T6 (150–180°C).^[1] Furthermore, the overaged treatment results in increased stability and performance when service involves exposure at elevated temperatures and to thermal fatigue.^[83]

Effects on Microstructure

Solubilization of precipitated phases is not the only microstructure feature which change as the casting alloys are heat treated. It is known that the morphology of intermetallic phases change when the alloy is treated at high temperature for long periods of time.^[53,84] Their results indicate that the morphology of β -phase platelets changes through concurrent fragmentation and dissolution at the plate tips, whereas α phase does not undergo any change. They conclude that temperature is more critical than time, once a minimum solution time is exceeded, and an optimum temperature of 535°C is quoted.^[84] This temperature might be too high for an alloy containing any amount of the complex $\text{Al}_5\text{Mg}_8\text{Cu}_2\text{Si}_6$ - CuAl_2 eutectic, see Figs. 23 and 24, and will be susceptible to an increase in porosity.^[53]

Solubilization contributes to modification of the Al-Si eutectic,^[45,48,85,86] as the sharp platelets of Si will be broken and rounded, Fig. 32, yielding to an increase in their roundness, Fig. 33, and in the mean free path between them,^[87] Fig. 34, which will contribute to improve physical^[37,87,88] and mechanical^[1,2,45-48,85,86] properties, but some troubles might arise during machining if the morphology of the silicon phase is fully rounded during heat treatment.

COMPUTER MODELING

Development of computer code to predict the behavior of a metal as it is poured in a mold has matured from an academic problem, in the early '60s and '70s, to a useful tool for the operating foundryman on the shop floor. Continuous improvement in hardware in terms of speed and cost have made this task easier, but there are still some limitations related to casting complexity, and to the amount of time involved in the numerous computations required to simulate the flow, cooling and solidification of a complex casting shape.

Fig. 32 Spheroidization of Si platelets during solubilization

Fig. 34 Change in mean particle spacing between silicon platelets with time

Modeling and simulation of a problem is based on the possibility of breaking it into its components parts, which will be small enough to be understood in sufficient detail. The aspects of the different parts can then be researched in an individual way, and when sufficient understanding of these has emerged, and integrated model of the whole problem is build upon this new knowledge. The capability to reproduce the behavior of such a model will depend on how finely the mechanisms of the individual components are understood, however, the advantage of this type of models is that they can now be modified, improved or scaled without loss of accuracy. Nowadays it is possible to simulate the casting process by solving the momentum, energy and continuity equations to obtain the local velocities and temperatures of the metal as it flows in a mold. Several authors^[88-97] have pointed out the applications of solidification modeling as well as its limitations and potentials.

Modeling Heat Flow

Evaluation of the heat flowing from the liquid metal into the mold has been from the beginning one of the most

important tasks in the simulation of castings. Two major techniques, which are the finite difference method (FDM) and the finite element method (FEM) are commonly employed to solve heat transfer problems.^[89,92–96] Both of them approximate the solution of differential equations of the initial-value or boundary type, which in the case of two-dimensional conduction is given by:

$$\frac{\partial T}{\partial t} = \frac{\partial(\alpha \frac{\partial T}{\partial x})}{\partial x^2} + \frac{\partial(\alpha \frac{\partial T}{\partial y})}{\partial y^2} + Q \quad (8)$$

where T is the temperature, t the time, α the temperature dependent thermal diffusivity of the material, x and y are the spatial coordinates and Q represents the change in temperature in the material due to phase transformation, which, in the case of solidification, is given by:^[92]

$$Q = L \frac{\partial X}{\partial t} \quad (9)$$

where X is the solid fraction and L is the latent heat.

The FDM divides the solution domain into many smaller regions called cells and, the governing differential equation is converted into one in differences^[98] which is applied at the centre of each cell. Figure 35 shows the case in which a body is divided into a number (m) of cells to solve the two-dimensional heat flow. Two schemes can be employed to evaluate the gradients within the body by transforming Eq. 8. The first one calculates the temperatures at the centre of a cell at the end of a given cycle of computation as a function of the temperatures of the surrounding cells at the beginning of the iteration, such changes are calculated by:

$$\frac{T_a^* - T_a}{\Delta t} = \alpha \left[\frac{T_b - 2T_a + T_c}{(\delta x)^2} + \frac{T_d - 2T_a + T_e}{(\delta y)^2} \right] \quad (10)$$

where Δt , δx and δy by replace the differential terms $\partial t, \partial x, \partial y$, T_a , T_b , T_c , T_d , and T_e , are the temperatures at the centre of cells a , b , c , d and e , at the start of the iteration,

Fig. 35 Division of a piece to calculate two-dimensional heat flow

T_a^* represents the temperature at the centre of cell a after Δt has elapsed: α is evaluated at T_a .

The second scheme calculates the temperature at the end of the iteration as a function of the temperatures at the end of the cycle of their surrounding neighbors:

$$\frac{T_a^* - T_a}{\Delta t} = \alpha \left[\frac{T_b^* - 2T_a^* + T_c^*}{(\delta x)^2} + \frac{T_d^* - 2T_a^* + T_e^*}{(\delta y)^2} \right] \quad (11)$$

The former one is known as the explicit formulation and has the advantage of being faster and easier to employ, the second one, implicit, requires that all the local equations are collected to form a system of algebraic equations, that also include the boundary conditions, in terms of the unknown variables. The values of these variables are found by solving this matrix system. One limitation of FDM is that curved boundaries cannot be adequately represented, and the software has then to use very small cells, which increase their number, and the time involved in the simulation of a single cast.

The finite element method employs subdivision of the solution domain into regions of different elements of more convenient shapes (such as triangles and quadrangles) that are connected at their nodes. The method uses approximation theory to evaluate the behavior in each element and the action of the differential equations are approximated by their values at the nodes. The differential equations are transformed into finite element equations with the use of the variational principle or the weighted residual methods.^[99] The local equations are collected to form a global system of ordinary differential or algebraic equations (incorporating the boundary conditions). FEM has the advantage over FDM that non-linear problems involving heterogeneous materials can be addressed. Curved and moving boundaries can also be modeled with FEM.

Fluid Flow Modeling

For industries where different shapes occur frequently, and for large components where the fill-time is an important part of the solidification time, the thermal response of a mold or die is important to the thermal field of the liquid metal, and on its solidification and production of defects. Two different cases can be considered, the first one in which very slow filling occurs and flow is nearly laminar and thermal conduction is dominant, and the more usual case where the effects due to turbulence should be taken into account.

Fluid flow modeling might be the only way to know what is going within the mold, since it is difficult to make direct observations inside them, because the metal and mold are opaque, the temperature is high and the conditions are far from stationary. Moreover, modeling can give information about velocity and pressure gradients within the molten metal, which cannot be obtained by direct observation.

When direction of flow is dictated by geometry, as in the case of flow in sprues, runners and gates, the computational techniques more employed are those based on energy balance, whereas modeling flow in open cavities requires the solution of the Navier–Stokes equation by the momentum balance method.^[90,91,95]

Fluid flow within a cavity during filling is transient, the amount and location of liquid changes rapidly with time, and the location of the free surface should be an integral part of the calculations. Most of the software developed to account for the location of the free surface are based on the Mark and Cell algorithm.^[90,91,93,95] This method divides the system into a number of cells, and sets a series of imaginary markers (or fluid function values) are introduced to represent the location of the fluid at any instant. The velocity field of the fluid is calculated and the markers are moved (or the fluid function is updated) to separate the regions considered to be filled by the liquid from those empty. The procedure is repeated from the beginning, when the cavity is empty, until it is filled. Figure 36 shows an example of such when the boundary is delimited by fluid function values.

Microstructural Evolution

Casting is the unusual manufacturing process in which modeling activities are well developed at different scales for the multiple physical mechanisms and processes involved: nucleation, dendritic growth, liquid flow through semi-solid dendrites, latent heat evolution, etc., although not all the mechanisms are as well developed in all alloys.^[92,94,96]

Shaped casting thus provides an excellent illustration of a manufacturing process where modeling has produced a very wide variety of scientific and industrial tools. Casting has to couple macroscopic modeling of geometric shapes with micro-models of materials processes. For a shaped

piece, its morphology itself is a property of interest only at sizes above 1 mm, whereas growth of nuclei involve phenomena at atomic scales.^[92,94,96,100–102]

Nucleation

Nucleation modeling depends on the alloy and the casting procedure, if the nucleation potential of the alloy cannot be controlled within a small range then no model will be of much help. If nucleating agents are added the availability of nucleating sites will depend only on the distribution and movement of these particles and not on any stochastic process.^[96] Only recently have modeling algorithms been developed to predict the probability of individual nucleation colonies, so an overall behavior can be deduced from modeling such events.^[100]

Growth Models

Modeling growth of individual microstructural features involve different scales, a grain is an order of magnitude larger than the primary dendritic spacing, which is also an order of magnitude larger than the secondary arm spacing. Modeling of the shape of dendrites has been conducted at scales of less than 10 μm and reproduces stable and unstable behavior and the transition between cellular and dendritic growth patterns,^[103,104] which has been incorporated into a physical-based dendrite model.^[100]

Growth models are required to obtain more sophisticated transport solidification models which are based on experimental data or in simple solid-fraction latent heat models. A series of attempts have been made to predict grain formation and growth since the original work by Scheil.^[105] A particular problem when modeling growth is that of impingement, since a dendrite, grain or colony will be able to enlarge as long as it does not touches another growing structure.

Defect Prediction

Shaped castings commonly contains fluids, so the most important defects are those which can lead to leaks, either by loss of strength of directly through pores or pits near the surface. It is common practice to predict porosity based on the criterion proposed by Niyama et al.:^[106]

$$N = \frac{G}{R^{0.5}} \quad (12)$$

where N is an index which will indicate the occurrence of porosity when a critical value is exceeded, G is the maximum thermal gradient computed between a cell or element (depending if FDM or FEM is employed) and its neighbors, and R the cooling rate at the cell or element, it should be mentioned that both R and G are those at the solidus temperature. A disadvantage of such criterion is that porosity can only be determined in the piece after the simulation

Fig. 36 Positioning of the liquid boundary obtained with the fluid flow function (0 = full, 1 = empty)

has finished, and not during modeling, which might affect the results since porosity will affect heat transfer in the volume surrounding it.

Interfacial Effects

As liquid metal is poured into a mold, it will establish intimate contact with the walls, where heterogeneous nucleation will be promoted, and the solid micro structure will start to develop. Heat transfer to the mold will not only be controlled by the thermophysical properties of the material from which the mold is made, but also by the type of coating or paint used to protect the wall and avoid adhesion between the liquid alloy and the mold.

The heat transfer conditions during solidification are complex because the boundary conditions change with time. As the metal solidifies, it shrinks, forming an air gap at the interface, which reduces the heat transfer rate,^[107-110] but also, solidification proceeds through a series of reactions which result in different microstructures, each of them with different properties, for instance, it is known that thermal conductivity is higher for solid aluminum than liquid.^[111]

Figure 37^[110] plots the heat transfer coefficients, as a function of time and temperature, which were found in a series of experimental trials carried out with an hypoeutectic Al-Si alloy cast on top of a steel plate, which was protected by either of two different paints (ceramic and graphite), and was cooled at its bottom either with water or air. The values recommended by a developer of computer code^[112] are included for comparison.

The variation of the heat transfer coefficient shown in Fig. 37 can be rationalized in terms of the diagram shown in Fig. 38. The low heat transfer rates found at the early period of solidification can be due to the lower conductivity of the liquid as compared with the solid (a). The transfer rate will be increased as the dendritic network

develops (b), because nucleation occurs at the interface and, as the individual dendrites grow and develop the secondary branches, the transfer rate will be enhanced. The decrease in the heat transfer coefficient as the eutectic starts to form (c) might be due to shrinkage of the solid crust, the establishment of a layer of lower thermal conductivity (since thermal conductivity of Si is lower than that of the Al), or by the heat evolution produced by this reaction. Once the interfacial layer has fully developed, the transfer rate will decrease as the gap generated by the shrinkage grows (d).

A Simulation System

A casting simulation system should consist of three distinct components:

- Pre-processing.
- Processing.
- Post-processing.

The first step to simulate casting is the simplification of the physical phenomena by realistic assumptions and basic observations. This step is conducted during pre-processing by taking a solid model of the piece to be simulated, the model is then divided into small pieces (cells or elements) of appropriate shape. The thermo physical properties of the liquid, as well as of those other materials forming part of the mold are set, this can be done by a series of tables in which the temperature dependence of the variable is interpolated, or by the introduction of different parametric equations. The boundary conditions can also be set in the same way, see Fig. 37. The time required in the simulation can be shortened in pieces in which a symmetry plane is found. Figure 39 shows, as an example, the numerous small cells into which a cylinder head should be divided to simulate its casting.

Fig. 37 Heat transfer coefficients at different interfaces found when casting an aluminum alloy on top of a metal mold^[110,112]

Fig. 38 Solidification mechanisms which affect the heat transfer rate to the mold

Processing implies the solution of the different set of equations employed to model the casting problem. A comprehensive model should account for fluid flow and heat transfer during filling the mold, fluid flow, heat and mass transfer during solidification, as well as the thermal and mechanical stresses developed during cooling. These macro-scale phenomena should be coupled with micro-scale mechanisms (nucleation, growth, segregation, etc.) to obtain sensible results.

Post-processing in mathematical modeling and computer simulation is normally referred to the activities involved in assembling the data produced during processing in order to visualize the process, an example of such is shown in Fig. 40, in which the thermal field obtained during solidification of the piece shown in Fig. 39 are plotted.

Fig. 39 Example of the numerous cells required to simulate a cylinder head

NOVEL PROCESSES

Continuous development of castings in order to obtain better properties and reduce processing costs and times has resulted in different non-traditional processes, among them, the most important are semisolid or slurry processing and particle reinforced casts.

Semisolid Processing

Metals are traditionally processed either in liquid or solid state. Processing metals while there are a mixture of solid particles dispersed in liquid is a relatively new technology which is experiencing a rapid growth.^[113,114] Processing of materials in semisolid state offers distinct advantages over similar net-shaping methods. These benefits arise from the rheologic properties of the material which lie between those of a pure liquid and a pure solid. Two distinctive names are given to the process depending on whether the material is injected into a die (thixocasting) or shaped between closed dies (thixoforming), Fig. 41.

The raw material in these processes is melted and allowed to cool and solidify while its structure is altered by mechanical or electromagnetic means. The process at this stage is called rheocasting since the melt is rheologically manipulated during the liquid-solid transformation. The parts being prepared in this way are then reheated to a temperature in the mushy region and processed into complex shapes.

Semisolid processing offers several advantages over liquid metal processes, among them are the reduction in porosity as the liquid fraction to solidify is just a fraction, the heat to extract from a piece is less, which allows for higher productivity and shorter cycles, the semisolid metal has a higher viscosity than the liquid, which allows

Fig. 40 Thermal field computed during solidification of the piece shown in Fig. 39

Fig. 41 Schematic diagrams of the thixocasting and thixoforming processes

for filling the die cavity in a non-turbulent fashion, minimizing the potential for entrapping air. These characteristics allow for production of pressure tight and structural components employed in the automotive industry.^[115]

Particle Reinforced Castings

Castings reinforced by particles are special formulations of one or more materials in liquid metal in which tailored properties are achieved by systematic combination of different constituents. Modern reinforced castings differ from traditional processes in the sense that any volume, shape or size of reinforcement can be introduced into the material,^[116,117] Table 8.

A basic requirement for processing these materials is the intimate contact and bonding between the reinforced particles and the molten alloy. This is achieved by mixing the dispersoids into the melt or by pressure infiltration of molten alloys into preforms of a ceramic phase. Due to the poor

Table 8 Dispersoid used in cast aluminum alloys^[116,117]

Dispersoid	Dispersoid size (μm)	Amount of dispersoid (%)
Graphite flakes	20–60	0.9–1
Graphite granules	15–100	1–8
Alumina particles	3–200	3–30
Silicon carbide particles	16–120	3–20
Silicon carbide whiskers	5–10	10
Mica	40–180	3–10
Silica	5–53	5
Zircon	40	0–30
Magnesia	40	10

wetability of most ceramics by molten metals, intimate contact between particles and alloy can be promoted by using external forces. Various mixing techniques have been developed to introduce the dispersoids in the melt, among the most used are: addition of particles to a vigorously agitated bath, gun injection of particles in the melt, additions of powders to ultrasonically or electromagnetically stirred alloy, and centrifugal dispersion of particles in a melt.

Aluminum alloys have been used as matrix materials in a wide variety of composites containing graphite and ceramic particles, glass microspheres and ceramic fibers.^[117] The microstructures of these aluminum-silicon hypoeutectic alloys, Fig. 42, show that the primary aluminum dendrites avoid the added particles (graphite and silicon carbide in this case), and they grow by rejecting solute into the melt, while the ceramic particles will restrict diffusion and fluid flow. Primary silicon and the eutectic aggregate, in the other hand, will tend to concentrate on the particle surface.^[116]

Castings: Ten Rules for Good Castings

John Campbell

Metallurgy and Materials, University of Birmingham, 6 Old Market Court, Market Street, Ledbury, Herefordshire, HR8 2GE, United Kingdom

Abstract

The Ten Rules are a checklist of the conditions necessary for the production of successful castings, particularly dealing with the metal quality, with a view to achieving a casting with minimal, preferably zero, faults. The first five Rules specify the conditions to avoid entrainment defects, particularly bifilms and bubbles. The remaining Rules deal with the provision of feeding, avoidance of convection, chemical segregation, and residual stress, and the provision of pickup locations for machining.

Keywords: Bifilms; Casting; Defects; Entrainment; Machining; Rules; Segregation.

INTRODUCTION

The Ten Rules are a checklist of the fundamental requirements for the manufacture of a successful metal casting. Because of the immense complexity of the casting process, these Rules are necessary but not exclusive. Many factors are already on the known list of requirements, representing the normal preoccupations of the foundry, such as the alloy composition and its temperature. The Ten Rules are those additional fundamental requirements, many of which happen to be frequently overlooked.

The checklist of Rules is necessary because at the time of writing, most castings are poured, unfortunately, under gravity. The action of gravity is to accelerate the pouring liquid to speeds well above the critical speed at which the melt remains safe from entraining its surface. At the unwanted high speed, the liquid metal is hypersensitive to even tiny errors in the design of the channels which guide the flow of the metal into molds, resulting in the entrainment of air and oxides into the flow. The generated bubbles as pores, and double oxide films (bifilms) as cracks, are the fundamental standard defects impairing the properties of most cast metals, particularly Al alloys.

The bifilm defects perhaps need some explanation. They are formed in turbulent conditions, in which the liquid metal jumps and splashes. However, because the liquid metal surface is usually covered with a solid oxide film of aluminum or chromium oxide (or other high melting point oxide) each time a splash or droplet impacts on other splashes or droplets, the two meet oxide to oxide. The oxide surfaces are actually dry, and non-wetting, so that no bonding in the impact area is possible. The two films constitute a “bifilm” whose central unbonded interface now acts as a crack in the liquid. Turbulent pouring of metals can fill the liquid with cracks (Fig. 1). The cracks are easily opened by shrinkage, leading to shrinkage porosity, or gas,

leading to gas porosity. They can also open by tensile stress, forming hot tears or macroscopic cracks.

Additional important problems can arise from other relatively little-known phenomena, including convection, segregation, and dangerously high stress from inappropriate heat treatment. In many cases, the failure to meet only one Rule can result in failure. To ensure success every time, every one of the Rules is required to be fulfilled.

RULE 1: START WITH A GOOD QUALITY MELT

Immediately prior to casting, the melt shall be prepared, checked, and treated, if necessary, to bring it into conformance with an acceptable minimum standard. Preferably, prepare and use only near-defect-free melt.

For the dense metals and their alloys based on copper, nickel, and iron, the population of entrained defects, bubbles and bifilms, detrains quickly by flotation. A ladle of such metals can clean itself of a major proportion of its major defects within minutes. For steels, the result is seen as their excellent elongation to failure, generally in the region of 50%. This excellent toughness contrasts with that of aluminum alloys, whose elongation values in the as-cast condition are usually in low single figures. This poor performance of aluminum arises because bifilms in Al alloys have nearly neutral buoyancy, taking hours or days to settle out. A good quality melt is therefore much more difficult to achieve for Al than for steel. It is easy to fail the first Rule when attempting to make aluminum alloy castings.

There are ways to upgrade the quality of Al alloy melts. Rotary degassing has somewhat mixed benefits because its beneficial action reduces hydrogen and large bifilm skins from the surfaces of the charge materials; it also tends to increase the numbers of fine bifilms, probably

Fig. 1 The messy situation during turbulent pouring, in which bifilms and bubbles are entrained into the liquid metal. The bifilms show pockets of entrapped air, and the larger bubbles show sufficient buoyancy to rise, but may or may not escape from the metal

from the bursting of the argon bubbles at the surface of the melt; and the waft of air can enter at that instant to oxidize the internal surface. The bubble then collapses inward, the opposite sides meeting to form a bifilm defect. Thus, after early elimination of the relatively few major oxide skins (a valuable benefit) and the hydrogen in solution (another benefit), the process then starts to manufacture thousands of smaller oxide bifilms which is almost certainly harmful to properties. An optimum rotary degassing treatment has not so far been studied.

One of the completely positive actions is the addition of grain refiners based on Ti+B. Interestingly, the grain refining action is relatively unimportant, but the action of Ti compounds to precipitate on bifilms, and sink them to the bottom of the ladle, is a major benefit, cleaning the melt from bifilms prior to casting, and thereby achieving greatly improved properties.

RULE 2: AVOID TURBULENT ENTRAINMENT OF THE SURFACE FILM ON THE LIQUID

The liquid metal front should not go too fast. The safe maximum meniscus velocity is 0.5 m/s for Al and its alloys. At this velocity, the melt has just insufficient energy to damage itself. Flow takes place quiescently. At any higher speed, the melt has enough energy to create surface turbulence, jumping sufficiently high to fold in its own surface as it falls back under gravity (Fig. 2).

The 0.5 m/s maximum velocity requirement also implies that the liquid metal must not be allowed to fall more than a critical height corresponding to the height of a sessile drop of the liquid metal. The height of a sessile (sitting) droplet, approximately 12.5 mm, is precisely the height from which a falling liquid will be accelerated from zero speed to 0.5 m/s. This ridiculously small fall effectively means that all falls of the liquid are required to be avoided

Fig. 2 The regimes of ingate velocities. The zero or near-zero velocity condition is safe, but problematical for production; the high velocity creates defects, particularly during the fall back of the metal under gravity; the optimum fill rate at which surface tension can hold the metal front intact against the height of the spreading droplet is in the range 0.5–1.0 m/s. No defects can be entrained at these low filling speeds

if turbulence, and the consequent creation of bifilms is to be avoided.

RULE 3: AVOID LAMINAR ENTRAINMENT OF THE SURFACE FILM ON THE LIQUID

No part of the liquid metal front should come to a stop prior to the complete filling of the mould cavity. In other words, The liquid metal front (the meniscus) should advance continuously.

The avoidance of laminar entrainment of the melt surface is achieved by arranging for conditions in which the meniscus expands continuously. In practice, this means progress only uphill in a continuous uninterrupted upward advance (i.e., in the case of gravity poured casting processes, from the base of the sprue onwards).

The advancing liquid metal meniscus must be kept “alive” (i.e., moving). While continuously moving, the oxide film on the advancing front of the liquid metal continuously splits open, moving sideways, but is immediately replaced by the formation of new film. The splitting and separating action of the film on the advancing metal meniscus removes the thickening film from the meniscus, transferring it sideways, where it finally becomes the skin of the casting.

If the liquid stops, the surface film on the meniscus now continues to thicken. If separate “live” streams arrive from a different direction, the thin film on the newly arriving metal will meet, impacting on the thickened stationary film, and be incorporated into the casting as a bifilm, usually in the form of a through-wall crack.

On a horizontal section of a casting, if the melt advances as a stream or river, only the meniscus at the front of the stream continues to move; in contrast, the “banks” of the stream are stationary. The banks therefore continue to

thicken their oxide film. When metal arrives from different directions, arriving at the banks of the stream (from “outside” the banks), a serious double film crack is again formed.

A “waterfall” of metal, overflowing to fill a region of the mold, will form a stationary oxide skin around the falling stream (this phenomenon of a melt pouring through a “tube” formed from its own oxide is commonly seen when liquid metal is poured from a ladle). As the melt rises around the falling stream with its surrounding oxide tube, the rising meniscus rolls up against the surface of the tube, effectively creating a vertical tubular bifilm. Such tubular cracks from waterfalls have been observed in Al castings.

To ensure the continuous, uninterrupted, upward advance of the meniscus, a number of conditions have to be fulfilled:

- Only bottom gating is permissible (otherwise there has to be a fall somewhere in the mold cavity. Unfortunately, this is not easily met for many two-parted molds necessarily gated on the mold joint, which gives frequent problems in some alloys).
- No falling or sliding downhill of liquid metal is allowed (this forms streams).
- No horizontal flow of significant extent (rivers and streams again formed, with bifilms formed against their ‘banks’).
- No stopping of the advance of the front due to arrest of pouring, or arrest by overflows or waterfalls.

RULE 4: AVOID BUBBLE ENTRAINMENT

No bubbles of air entrained by the filling system should pass through the liquid metal in the mould cavity.

Avoidance of bubbles may be achieved by

- Contact pouring to eliminate air entrainment into the sprue.
- Or properly designed offset step pouring basin together with the use of a stopper to fill the basin to its designed fill level prior to allowing the melt to enter the sprue. (The offset step basin is excellent, eliminating most bubbles, but cannot detrain the bifilms which are usually entrained during the pouring into the basin itself.)
- Use a “naturally pressurized” filling system design. This design of filling system uses the design of channels that just, and only just, fill with metal, but uses the effect of friction in the system to provide a gentle, minimal pressurizing, but naturally occurring, condition throughout the system to prevent the entrainment of air.
- Avoid the use of a “well” at the base of the sprue (or any other feature that increases the area of the filling channel so as to lose pressurization of the metal by the walls of the containing channels).

- Use vertical gates taken off filters over the runner, with runner extensions to allow bubbles to bypass under the filter (rather than forced through the filter). The bubbles should progress into irreversible bubble traps such as a cylindrical spinner.
- No interruptions to pouring can be permitted (on restarting a pouring action, a mass of air is necessarily taken down the sprue). These problems are often associated with the use of successive pours from multiple small ladles.

Any bubbles that enter the mold leave in their wake a long “bubble trail.” This is the sloughed-off oxide skin of the bubble, continuously manufactured as the bubble rises.

The trail is a long, collapsed, hollow oxide tube starting from the point at which the bubble first entered the metal (often about halfway down the sprue), proceeding through the runner and gates, and eventually emerging at the top of the casting. The bubble trail is a massive defect. It can act as a crack, and its hollow center is an excellent leak path. In very turbulent filling systems, hundreds of bubbles plus their bubble trails can seriously damage a casting.

Bifilms and bubbles can sometimes be identified separately on a dye penetrant test. Bifilms usually show indications as faint red traces, decorated with spots of slightly darker red where pockets of porosity were entrained by the bifilms. Bubble trails, however, may reveal themselves as large diameter, deep red circular spots as a result of the volume of dye which they can absorb, probably penetrating many centimeters or more, deep into the casting.

RULE 5: AVOID BLOW DEFECTS

No bubbles from the outgassing of cores or molds should pass through the liquid metal in the mould cavity. Cores to be demonstrated to be of sufficiently low gas content and/or adequately vented to prevent bubbles from core blows. Chills require to be warm and dry, and/or preferably coated with a permeable paint plus venting grooves. No use of clay-based core or mold repair paste can be allowed.

When the hot metal surrounds the cores, they heat up, expanding (i) the gases that they contain, plus (ii) boiling volatiles from the binder. Eventually, the pressure of gases inside the core may exceed the hydrostatic pressure of the liquid metal surrounding the core. At that point, a bubble can emerge from the core and float up through the liquid metal. Its passage through the melt leaves a characteristic bubble trail, because the volatiles, mainly steam, are highly oxidizing. It represents therefore a potentially serious risk of a leakage defect. As the bubble rises toward the top of the casting, its rather late arrival (as a result of the core taking time to heat and “blow”) usually means that a thickness of solid skin of the casting has already formed. The rising

gases are therefore completely trapped in the casting, occupying a uniform distance under the top surface, depending on the thickness of the solidified metal skin.

Perversely, attempts to repair faulty cores with a core repair paste are highly counterproductive. The pastes are usually based on clays, which contain water, but are impermeable to gases. When the liquid metal covers a core repair, its water of crystallization boils, but cannot escape through the repair back into the core to reach a core print or other escape. It is forced to boil off through the liquid metal.

Condensation on metal chills can also lead to blow defects in the same way. Blows from cores (and sometimes from chills) can be checked by partly dismantling a mold, taking off the cope or cutting away other upper features, so that the entry of the liquid metal can clearly be seen, and watched carefully as it covers core after core, until filling is complete. The filling event should be recorded on video so that details can be replayed for careful study and demonstration of fault-free behavior to a customer.

RULE 6: AVOID SHRINKAGE

Feed the casting to avoid solidification shrinkage problems if necessary.

There is much to say about this Rule; it has many implications:

- Feed only if necessary—many light alloy, thin wall castings do not require deliberate addition of feeders—the casting freezes sound naturally by (i) freezing while filling together with (ii) collapse of the walls (a “solid feeding” effect) giving microscopically thinner walls (well within the dimensional specification).
- Feed downhill, taking advantage of gravity (note that feeding direction is opposite to filling, since filling should always be uphill, against gravity), using feeders placed as high as possible on the casting.
- No feeding uphill, especially in larger section thickness castings because of (i) unreliable pressure gradient and (ii) complications introduced by convection.
- Demonstrate good feeding design by an approved computer solidification model.
- Control (i) the level of flash at mold and core joints (which can introduce fortuitous chilling and changes in feeding conditions), (ii) mold coat thickness in metal molds, and (iii) temperatures of metal and mold.
- On radiographs and polished sections, take care not to confuse *apparent* shrinkage indications with bifilm and bubble trail tangles (which are far more common).

RULE 7: AVOID CONVECTION

Avoid the damage caused by thermal convection during freezing.

Convection in castings is not widely understood but can give serious production problems in the special cases where convection effects take place.

Assess the freezing time in relation to the time for convection to cause damage. Fortunately, both thin- and thick-section castings automatically avoid convection problems. For thin sections, the drag effect on the liquid from nearby walls helps to dampen all motion of the liquid, making convection difficult. In addition, freezing occurs quickly before convection can get under way. Conversely, for thick sections, convection acts favorably, reversing the unfavorable temperature gradient which often exists immediately after filling of the mold. The slow freezing rate allows time for the cold metal at the top of the mold and the hot metal near the gates in the base, to slowly exchange positions, so that the temperature gradient becomes favorably oriented with, finally, hot at the top and cold at the bottom of the mold.

Unfortunately, for intermediate sections, the migration of the hot metal occurs, while parts of the casting are attempting to solidify, and the surging high-temperature liquid can sometimes remelt large sections of the casting, making most computer predictions invalid and giving problematic freezing conditions that are not easy to feed, resulting in difficult-to-explain shrinkage problems.

For intermediate castings, convection problems can be reduced by

- i. Avoiding convective loops in the geometry of the casting and rigging. This may mean shutting off one or more of multiple vertical gates from under the casting; or for investment castings, the use of ceramic plugs to cut convective loops formed by strengthening struts between the casting and the sprue.
- ii. Avoiding feeding uphill.
- iii. Eliminating convection by rollover after filling

RULE 8: REDUCE SEGREGATION

Confirm macro segregation to be within limits of the specification, or agree out-of-specification compositional regions with customer.

Fortunately, many common engineering alloys do not suffer from significant macro segregation problems, so that the chemical elements are sufficiently uniformly distributed throughout the casting. Some notable common exceptions appear with Al alloys that contain copper, and in steels, carbon segregates to regions under a top feeder in sufficiently heavy castings, particularly ingots. Channel segregates (“A” and “V”) occur in heavy steel castings and can be troublesome in Ni-base alloys in single crystal turbine blades as a result of their lengthy freezing times. Chilling the casting to reduce freezing times may help, but may not eliminate the problem.

RULE 9: REDUCE RESIDUAL STRESS

No quenching of light alloy castings into water (cold or hot) following solution treatment.

Stress well over the yield stress is generated in castings, especially those with internal cavities formed by cores. This is because the quench water cannot easily penetrate a casting at a temperature well above its boiling point (any water entering the cored passageways is converted to steam, which expands explosively, forcing out any water which is attempting to enter). The cooling of internal features is therefore significantly delayed. The ensuing temperature differences between the inside and outside of the casting create major strains that can cause the casting to crack either in the quench or later during service, when additional service stresses are applied.

Polymer quenchants and forced air quenches are significantly less severe in their quenching action than water, and may prove to be acceptable if the consequential casting stress can be shown to be negligible. For light alloys, it can be shown that the modest loss of properties (approximately 5%–10%) of quench and aged Al alloys when air quenched is more than compensated by the reduced loss of effective properties due to water quenching (which can be shown to exceed 50%).

RULE 10: PROVIDE LOCATION POINTS

All castings to be provided with agreed location points for pick-up for dimensional checking and machining.

The agreement on location points needs to include pattern-makers (tool makers), foundry personnel, and machinists.

Non-agreed techniques for picking up a casting for machining are a universally experienced and efficient way to scrap every casting that enters the machine shop, through no fault of the machine shop. The machinist needs to *agree* on how the casting is to be picked up for machining.

This Rule is beginning to be outdated as a result of the rapid expansion of electronic and optical techniques linked to robust software. Even so, when dimensional problems occur in the foundry, associated with either the tooling or the casting, cast-on datums can be a great benefit. Furthermore, the use of specific locations greatly facilitates the pickup mechanism as a result of such features being recognized by all parties, especially those involved with the dressing of the castings, who are encouraged to treat such features with respect.

Chemical Milling of Aluminum

Bruce M. Griffin

The Boeing Company, St. Louis, MO, United States

Abstract

Chemical milling involves the development of etchants and masking agents for the manufacture of filter elements for internal combustion engines, cut recesses in bearing journals, creation of printed circuits, manufacture of large structures used in the aerospace industry and many more applications. This article will address: chemical milling process steps, overview of maskants, tooling, area rules, overview of etchants, quality issues, and material selection for tanks and part racking.

Keywords: Chemical milling; Etchants; Maskants; Selection of compatible materials; Tooling.

INTRODUCTION

Perhaps the hallmark of any useful manufacturing process is its longevity. The origins of the chemical milling process can be traced back to the discovery of organic acid, followed by the discovery that the acids could be used to encourage corrosion.^[1] Once maskants were developed that allowed selective exposure to the corrosive liquids, the chemical milling process was essentially defined.

The earliest written evidence of deliberate use of etching on iron appears in a fifteenth-century English manuscript.^[1] The manuscript describes an etchant consisting of salt, charcoal and vinegar and a “maskant” of linseed oil paint. The paint was brush applied in the required pattern, and later the etchant was applied to all unprotected areas. The use of chemical etching as a technique for engraving weapons and body armor became more widespread in the early fifteenth-century. Weapons and body armor were forged as hard as a craftsman’s engraving tools, hence the old engraving technique was quickly replaced chemical etching process.

Craftsman employing chemical etching techniques were faced the same problems experienced in modern day chemical milling operations. Maskants developed by the sixteenth-century were an amalgam of wax, resins and asphalt.^[1] After applying the maskant by brush the craftsman would work the maskant with scribing tools consisting of needles and scrapers.^[1] Once the masking work was completed the etchant would be applied drop by drop and perhaps moved about with a brush to move the etchant to the precise locations necessary. Just as today, the craftsman pondered problems such as poor maskant adhesion, or complete maskant failure. Corrections for such problems included hand polishing to blend-in chemical burns, or pits, and perhaps adjusting a design to cover areas damaged by maskant failure.

The chemical etching technique as developed for armor etching also found use in the early printing industry and had profound affect on graphic printing.^[1] The primary advantage of an etched line over that of an engraved line is that the etched line is produced without an upstanding burr.

In more recent times the chemical milling process has been employed to manufacture filter elements for internal combustion engines, cut hard or thin materials that challenged conventional mechanical techniques, cut recesses in bearing journal to facilitate bearing lubrication, create printed circuits, and facilitate the manufacture of large metal structures for the aerospace industry. Variants of the chemical milling are used primarily in the electronics industry and the aerospace industry.^[1] One important spin-off of chemical milling technology is its use to manufacture intricate replacement parts for the human body.

In 1953 application of the chemical milling technique for aluminum was developed by Manuel C. Sanz and a group of manufacturing process investigators at North American Aviation in California, USA.^[1] The team developed maskants and etchants that could be used to produce consistent surface finishes on formed aluminum sheets. The use of a closely adhering maskant and etchants to create exact pocket dimensions and structurally useful ribs was essentially the first time the process had been used as a structure forming technique for aerospace applications. Before the chemical milling process, sheet metal structures for aerospace applications were created by forming two or more identical parts; routing one or more parts to create lightening holes, then joined all parts with rivets or threaded fasteners. With chemical milling one part is formed from a thicker substrate, then selected areas are removed by etching to create a lighter and stronger part without the concerns of sandwich or crevice corrosion.

Modern applications and uses of aluminum chemical milling include:

- Stock reductions to create material dimensions not available from metal suppliers or rolling mills.
- Stock reductions to reduce web thickness on machined components.
- Selective metal dissolution from sheet material to reduce part weight.
- Selective metal dissolution from sheet material to accurately locate structural features such as land or boss areas for mating parts or a pass-through.
- Tapering to create special part features or shim stock.

Covered in this chapter are:

- Five process steps of aluminum chemical milling.
- A review of maskant technology and solvent emission limits from masking operations.
- Discussion of tooling requirements, i.e. how to calculate removals and tooling offsets.
- A review of etchants used for aluminum chemical milling and appropriate waste disposal techniques.
- A review of materials best suited for tank and work rack construction.

CHEMICAL MILLING PROCESS STEPS

Pre-mask Cleaning

Aluminum must be cleaned to remove forming lubricants and soils before maskant application. Cleaning solutions must be capable of removing soils and preventing re-deposition of the soils. Techniques for pre-mask cleaning vary from a simple degreasing step by solvent wiping to elaborate processes that include aqueous degreasing, alkaline clean, acid pickle (etch), acid desmutting and application of a colorless conversion coat.

The minimum requirement for pre-mask cleaning is a solvent wipe. The preferred solvents have long been Toluene and Xylene, however emissions of both solvents are now regulated in the USA by the 1998 Aerospace NESHAP segment of the 1990 Clean Air Act.^[2] Other solvents such as Acetone or a new compliant solvent, Oxsol-100, are candidates for a pre-mask cleaning solvent.

Aqueous degreasing followed by alkaline or acid etching and an acid based desmutting solution represents a more consistent pre-mask cleaning process. Typically parts are degreased and alkaline cleaned before masking. A variety of proprietary aqueous degreasing and alkaline cleaning solutions are available. Most employ sodium hydroxide, sodium or potassium carbonate or bicarbonate, sodium metasilicate or trisodium phosphate. The user should select an aqueous degreaser and alkaline cleaner that effectively removes the soils encountered, and then

develop the cleaning process around the selected cleaner(s). Pre-mask cleaning will influence maskant adhesion, therefore, the cleaning process must be designed to make bare and clad aluminum surfaces appear the same to the maskant. To simplify basket loading, the cleaning process should accept mixed loads of bare and clad aluminum. Failure to properly condition the substrate for masking will result in large maskant adhesion variations, which will impact the quality of the finished chem-mill product. A pre-mask cleaning process should include aqueous degreasing, alkaline cleaning and deoxidize (Fig. 1). A more elaborate pre-mask cleaning process would include alkaline or acid etch following alkaline cleaning followed with an acid desmut or deoxidize step (Fig. 1).

Colorless conversion coat is recommended if the masking process is located at a remote site and shipping by truck is required. The conversion coat will impede surface corrosion if the parts should get wet due to rain or other mechanism during transfer. If a conversion coat for part protection is necessary the cleaning process should be extended by increasing the process time in the Deoxidizing solution, or adding a Nitric/Hydrofluoric acid, or alkaline etch before deoxidizing.

Maskant Application

Chemical milling maskants may be applied by a variety of techniques. Brushes or paint rollers may be used for small parts, or to cover small surface areas (1–2 ft²) on large parts. Sophisticated immersion coating or spray coating systems, that include solvent flash-off and drying ovens are used for large-scale operations. Depending upon the type of maskant selected, an attendant solvent emission control system may also be necessary. The maskant film must provide chemical resistance, abrasion resistance, tear resistance and reasonable adhesion to the aluminum substrate. The maskant film must maintain adhesion at the scribe line and prevent etchant leakage beneath the maskant. The maskant film must be uniform over the entire part surface, easy to scribe, provide contrast to highlight

Fig. 1 Pre-mask cleaning

scribed areas such that operators can see the scribe lines, and must retain ink or graphite markings. An ideal maskant film thickness for most chemical milling is 0.014 to 0.02 in. Solvent-based maskants perform well with 0.012–0.016 in. of maskant film; waterborne maskants perform best in the 0.016–0.02 in. maskant film thickness range.

The techniques most often used for maskant application are flow coating, immersion coating and spray coating. Maskant application by brush or roller is discouraged because this technique imparts coating defects such as bubbles and pinholes that must be repaired before chemical milling.

Flow Coating

The Flow Coating apparatus (Fig. 2) consists of a shallow tank, a low volume pump with flexible hoses and part racking devices. The parts are positioned over the tank and operators manually direct the maskant flow over the surface of the part from the top edge to the bottom. The maskant film is dried, then the parts are typically rotated and coated a second and third time to achieve a somewhat uniform film of proper thickness. The flow coating technique is most effective on medium sized parts (i.e. 3 ft wide $\times$ 10 ft long). Small parts and extrusions are usually dipped in the shallow tank. Flow coating large parts (10 ft wide $\times$ 30 ft long) is near impossible as it is difficult maintaining an even flow over large part surfaces. The frequency of maskant film defects such as bubbles and pinholes is greater with flow coating than either immersion coating or spray coating.

Immersion Coating

Immersion coating is ideal for small to large parts, particularly if the parts have complex contours. Immersion coating

provides the best quality maskant films for the broadest range of applications. Immersion coating is accomplished with a hoist, or lowering device located directly above a maskant tank. The parts are lowered into the maskant at a controlled rate, then are withdrawn from the maskant at a controlled rate (Fig. 3).

Immersion coating is easily linked to conveyance systems that can shuttle the coated parts through a drying oven and out to a load/offload work area where parts are rotated for additional maskant coats or removed for scribing (Fig. 4).

Immersion coating systems offer exceptional transfer efficiency as virtually all the maskant applied remains on the part, or is reclaimed as it drips back into the maskant tank. Immersion coating systems have been constructed with a drip pan included to catch and reclaim maskant that drips from parts. Including a drip pan should decrease coating cycle-time as parts do not have to remain over the maskant tank. In practice however, drip pans and the attendant pump(s) and piping require frequent maintenance. The more practical approach is to plan for mask line capacity such that sufficient drip time over the maskant tank (10–15 min can be accommodated).

The primary disadvantage of immersion coat systems is the initial cost of filling the maskant tank. Project planners must plan for either a large increase in overhead costs in the year that the tank is filled, or include the maskant cost as an expensive item in the project cost. A secondary disadvantage of immersion coating systems is the somewhat greater complexity of immersion coat tanks versus a flow coat tank. The immersion tank design must include means for maskant circulation by either pumps or a mixer apparatus to insure consistency of the maskant, and to sweep bubbles from the maskant surface between part immersion cycles. Tank design schemes successful for immersion coating systems are discussed in “Maskant Scribing” section.

Fig. 2 Flow coat apparatus for maskant application

Fig. 3 Immersion tank coat apparatus for maskant application

Fig. 4 Conveyance scheme for automated maskant application

Spray Coating

Spray application of maskant is a good maskant application technique for large flat parts and large parts with a mild contour (200 in. radius), (Fig. 5).

Spray coating of large parts with airless spray equipment can be accomplished with transfer efficiencies approaching 70–80%. Large, relatively flat surfaces limit excessive losses due to coating over-spray. An equally important aspect of spray masking is that maskant may be purchased and used in convenient quantities, thus there is less maskant inventory.

Preferred equipment for the spray application is airless or airless/air assisted. Spray gun and spray tip requirements are based on the application conditions and can be determined by the maskant supplier.

Spray application of chemical milling maskant is easily automated. A typical approach is for the part to pass

between opposing spray guns. Conveyance equipment designs can be identical to immersion coat systems, except a maskant spray apparatus is constructed instead of an immersion tank, (Fig. 5).

The primary disadvantage of spray application is that generally 4–5 coats are required to build the same maskant film thickness that can be applied in 2–3 immersion coats. Each additional coat requires a cure step as well, so actual cycle time for a completed spray applied maskant coating could be 67% longer than required for flow or immersion coating.

Maskant Scribing

Scribing for the general aluminum chemical milling application is accomplished with a standard X-Acto™ Knife, (e.g. #2 Handle with the #11 Stainless Steel Blade). Knife

Fig. 5 Spray apparatus for maskant application

Fig. 6 Scribe knife orientation

orientation relative to the tool is important. Poor scribing technique can result in mis-located chem-mill lines and substantial rework effort, (Fig. 6).

Chem-mill tools are constructed of sheet aluminum, sheet steel, or fiberglass.^[3] Scribe tools are typically located on the blank parts by pinning through pre-punched tooling holes. The tool is used as a guide for the scribe knife. Tools are generally color-coded to indicate multi-cut parts. Each airframe manufacture, and perhaps each chemical milling subcontractor has a color code to indicate cut number. The color is painted around the perimeter of each pocket. Operators mark the order of cut with a pencil or ink pen according to the color-code that appears on the tool (Fig. 7).

Parts with multiple chem-mill cuts may be processed by scribing and milling Cut 1, and then scribing and milling Cut 2 etc., or by scribing all pockets/lines with one tool set-up then sealing all lines for Cuts 2 and greater. To successfully complete the latter process a line sealer is applied by brush over all scribe lines that define preceding cuts

such as 2, 3, 4,... (Fig. 8). Scribe line sealers must prevent etchant leakage into scribe lines during the chemical milling process, but pull away cleanly as each pocket is pulled for further chemical milling. In addition line sealers must apply rapidly without foaming. Just as with chem-mill maskants line sealer choices are solvent-based or waterborne. Without question, recently introduced waterborne line sealer products are superior to their solvent-based predecessors.

Laser Scribing

The scribing process was automated with the introduction of a Laser Scribing Machine in the early 1980s at McDonnell-Douglas in St. Louis, Missouri. The machine was designed and constructed to scribe flat aluminum sheet stock only. More sophisticated multi-axis laser scribing machines were developed at the Douglas Aircraft Division of McDonnell-Douglas in the mid 1980s. Laser Scribing machines are now available from virtually any

Fig. 7 Chem-mill scribe tool application

Brush apply scribe line sealer product to protect scribe lines while pocket 1, then pocket 2 are etched.

Fig. 8 Scribe line sealer advantage

manufacturer of laser machine tools. CO₂ lasers are typically used for maskant scribing applications, and when possible the number of optics in the beam path should be minimized (Fig. 9).

Locating the laser close to the work surface, and moving the work surface instead of the laser, allows for a short beam path and should allow use of fewer optics and a low power laser.

Laser power requirements for maskant scribing are determined by the number of optics in the beam path, and the desired feedrates for laser scribing. For example, with one folding optic and an objective lens in the beam path, and a 400 in./min. (ipm) on axis feedrate a minimum of 200 W of laser power at the work surface is necessary. Less laser power will cut the maskant, however with a minimum of 200 W at the cutting surface, the laser scribing process can easily accommodate variations in maskant film thickness, and variations on work-piece flatness. Such

variations move the cut area in and out of the depth of field of the objective lens. Having adequate laser power is the most practical way of correcting for focus variations.

The light energy emitted from lasers in the 200–500 W range will reflect from the aluminum substrate, thus there is no damage to the substrate, but an enclosure should be constructed around the scribing machine. Since the laser vaporizes the maskant, there is an effluent generated by the process. Silica and quartz dust are possible by-products as is small amounts of styrene (from the styrene butadiene rubber typically used in maskants), CO and CO₂. Therefore, the process must be ventilated and emissions may be regulated by local air quality authorities.

Once the scribing machine is installed the supplier and user of the laser must work out an acceptable scheme for laser power control. As the machine slows for corners or splines in the part geometry, laser power must be reduced to prevent overheating of the maskant. A typical scheme is to run the laser in continuous wave mode while operating at feedrates greater than 100 ipm, then converting to laser pulse mode for lower feedrates as the machine negotiates corners.

Laser scribed lines are more difficult to line seal than knife scribed lines. Laser scribe line kerf width is 0.002–0.01 in. compared to 0.001–0.002 in. for a knife scribed line (assuming that a sharp knife is used) (Fig. 9). Waterborne scribe line sealers recently formulated for laser scribed lines have provided excellent performance. As with knife scribed lines the line sealer products should be flowed over the scribe lines with unidirectional brush or applicator strokes. Multi-directional brush strokes, or “painting” the scribing lines can draw the line sealer out of the scribe line, which will allow leaks at the scribe line during the etching process.

The primary advantage of laser scribing is the elimination of scribing tools – reduction in scribing time is significant for large parts only. Once part data has been

Fig. 9 Laser scribing chem-mill maskant

digitized, scribing automation can be easily expanded to include tooling hole location and final routing. Integrating chem-mill scribing with pre- and post chem-mill processes will eliminate requirements for all tools and sample parts. Hence, the manufacture and administration of many tools can be eliminated, plus part design changes can be incorporated in minutes instead of months.

For large part scribing, the expansion coefficient for metal or fiberglass scribing templates is sufficient to cause significant dimensional problems for long parts (20–40 ft long) when scribing is performed manually. Material used for scribing templates and work surfaces or holding devices must be selected to mitigate dimension changes that may occur due to differences in morning and mid-day temperature. Laser scribing allows for simple correction by using machine control unit functions for temperature compensation. Temperature compensation can easily be programmed into laser scribing machines to correct for problems with part/tool expansion or contraction.

Etching

Once scribing and line sealing are complete, parts are ready for etching. Parts are loaded into simple baskets or onto load bars. The preferred load position is diagonal, (e.g. 45°), but parts are frequently loaded in a vertical, or 90° position (Fig. 10). Parts horizontally (flat) in work baskets will carry larger amounts of etchant into the first rinse.

Parts are held in position by simply wiring the part to the basket structure, or by weighing the parts down with heavy screens. Small parts are generally placed in special dividers and held in place with heavy screens. If the chem-milled cut depth exceeds 50 mm, then good practice dictates stopping the process half way through the cut, and rotating the part

Two etchant types are used for aluminum chemical milling, Type I and Type II (Table 1). A preferred practice in some chemical milling operations is to mill 80% of the

Fig. 10 Basket loading

Table 1 Aluminum etchants

Aluminum etchant	Constituents	Operating temperature, °F	Etch rate mm/m/sec	Surface finish, Ra
Type I	sodium hydroxide sodium gluconate sulfur	180–205	0.5–1.2	120–250
Advantage: low cost				
Type II	sodium hydroxide sodium sulfide triethanolamine	180–225	0.8–3	40–70
Advantage: fast etch; excellent surface finish.				

cut in Type I Etchant, and finish the cut in Type II Etchant to improve surface finish.

Agitation of the etchant while parts are in process is good practice. Depending upon etch rate, some chem-mill operators refer to aluminum etchants as self-agitating, but agitation by mechanical means is necessary. Etchant agitation by air sparging is discouraged as injecting oxygen into the etchant will produce thiosulfate,^[4,5] which will in turn cause rough surface finish. Use of mixers, or pump(s) and fluid eductors is a preferred choice for etchant agitation.

Demasking

Demasking consists of removing all chem-mill maskant after all chem-mill cuts have been completed to the proper depth. Demasking is generally accomplished by simply pulling the maskant away from the substrate by hand. Specialized demasking tools have been developed for removing maskant from those substrates that exhibit excessive maskant adhesion (Fig. 11). The demasking tools are also valuable for expediting the demasking process. Other techniques such as dissolution of solvent based maskants (by immersing the part in the original maskant diluent) require long cycles times and expensive clean-up. Demasking by hand is the best compromise.

MASKANTS FOR ALUMINUM CHEMICAL MILLING

Masking for chemical milling is the most critical of the five basic process steps. The maskant type and application technique selected influence all aspects of the process. The pre-mask cleaning technique employed is dependent upon the maskant type selected. Overall process cycle-time is influenced by masking dry and curing time requirements and the maskant adhesion to the aluminum substrate. High maskant adhesion (adhesion in excess of 40–45 oz/in.) extends scribe and patch times and the time required final demasking efforts. High maskant adhesion contributes to employee discomfort and medical costs in the form of muscle strains and injury. High maskant adhesion contributes to increased scrap as thin gage material may yield and deform as large areas of maskant are pulled away during the demasking operation.

For aluminum chemical milling there are two maskant types, waterborne or organic solvent systems. The Environmental Protection Agency (EPA) established limits for control of emissions from chemical milling maskant application based on the etchant type used. If Type I aluminum etchant is used emissions may be 622 g/l (grams solvent per liter of liquid maskant applied). If Type II aluminum etchant is used and compliant maskants (waterborne or

**Fig. 11** Demasking techniques

Fig. 12 Mask tank designs for immersion coating

compliant solvent) are selected then solvent emissions are limited to 160 g/l. If Type II aluminum etchant is used and solvent-based maskant with solvent abatement equipment is selected, the abatement equipment must demonstrate a minimum 81% capture efficiency.^[6] The use of etchant types as a determinant for allowed solvent emission is based on performance failures of waterborne maskants in the Type I aluminum etchant.

Solvent-based chemical milling maskants are based on synthetic rubbers and one or a combination of organic solvent diluents. Filler materials and other additives are also included to enhance certain performance characteristics such as tensile strength, abrasion resistance or chemical resistance.

Development of organic solvent-based maskants began with Dr. Sanz and development of chemical milling as a modern manufacturing process. Solvent-based masking systems experienced some development pains, but the products evolved and improved and solvent-based maskants have remained essentially the same since the early 1980s. The lingering attraction to solvent-based maskants is that they are a known entity. Chemical milling operators can purchase solvent-based maskants from suppliers, or make solvent-based maskant. Formulas for solvent-based chemical milling maskants are available from resin suppliers. Solvent-based maskant formulae are mature and in terms of potential variations in pre-mask cleaning and aluminum etchants, solvent-based maskants are robust.

Early waterborne maskants employed natural rubbers emulsified in water. Chemical resistance was excellent, but the emulsion proved unstable and early waterborne maskants tended to fail in the mask tank in the form of uncontrollable viscosity or conglomerated rubber particles. Early arguments against waterborne maskant centered on the instability of the emulsions. Waterborne maskants that were mixed violently, or not properly maintained in the correct pH range, etc. could set-up into viscous lumps of rubber.

Equipment Designs

Strategies for use of such unstable maskants included improved equipment designs and different maskant chemistry. Early offerings of waterborne maskant were piloted in 500–1000 gal capacity tanks. The tank size selected for pilot operations allowed for reasonable evaluation and development cost, and allowed sufficient space for processing some production parts. Initial tank designs centered on simple rectangular tanks with circulation pump(s) connected to chambers located at opposing ends of the tank. Maskant was pumped from one chamber to the opposing chamber, hence maskant flowed across the tank surface (Fig. 12). Maskant flow problems are a potential problem with conventional tank designs. Maskant “skins”^{*} may appear in surface areas where there was insufficient fluid flow. Valves installed to allow some control of pump will produce little improvement.

In addition to the flow problems, pump selections can produce disastrous results. High shear pumps, such as gear or vein pump designs will destroy waterborne maskant. Within a short time high shear pumps will likely seize due to large amounts of conglomerated maskant collecting on pump internals. Diaphragm pumps are considered low shear pumps and they provide considerable improvement over the high shear designs. Diaphragm pumps do not correct flow problems in the tank, and they create their own maintenance problem. Diaphragm pumps are marginal for continuous duty service. This fact has been demonstrated in production facilities where diaphragms fail with regularity and fillers in the maskant quickly erode valve seats. Generally, complete pump rebuilds will be required at intervals ranging from 100–500 hr of pump operation.

^{*}Dried maskant that forms on the maskant surface in the immersion tank. Always occurs in areas of low or no fluid flow.

Attempts to extend the service interval increases the risk of catastrophic diaphragm failure, which will immediately contaminate the maskant with small air bubbles. Repairing pumps and “de-airing” maskant typically entails 16–24 hr downtime.

An alternate tank design for waterborne maskants as developed in the 1980s^[7] (Ref. Fig. 12). Mixers in a draft tube were selected to correct maskant flow problems, and the mixer and draft tube arrangement created weir flow at the down-flow mixer, a desirable attribute of the pump driven circulation design. Mixers are capable of moving large volumes of fluid at low pressure,^[8] hence the maskant surface could be quickly displaced and all bubbles and drippings from a previous part are quickly swept away. A successful waterborne maskant installation at the Boeing facility in St. Louis, Missouri (formerly McDonnell-Douglas) employs the mixer design (Ref. Fig. 12). A diaphragm pump is used for maskant transfer to the immersion tank, and a progressive cavity pump is used to circulate maskant through a bag filter.

Construction costs for either design are similar, however designs that use mixers will incur lower maintenance costs and less downtime. Design elements outlined in reference^[7] have been greatly simplified to reduce costs, while retaining all claimed attributes of the tank design.

Less complicated tank designs may be used. Designs that employ mixers for localized maskant blending have been used with limited success. For example, marine type impellers may be used and are least expensive, but are best used in draft tubes and with impeller tip speed limited to 11 ft/sec. Low shear impellers may also be used, but are less effective than marine type impellers in draft tube applications. Any mask tank design that will provide the following performance attributes will provide trouble free operation:

- Mix maskant volume to maintain viscosity and pH consistency.
- Sweep bubbles and drippings from the maskant surface between part immersion cycles.
- Create weir flow to break entrained bubbles and provide opportunity for maskant filtering.
- Create surface flow velocities sufficient to prevent the formation of large maskant skins.

Long Term Mixing Studies for Waterborne Maskants

Due to stability problems experienced with early waterborne maskants testing was conducted to determine the tank life of maskant products. Mathematical formulas were derived to estimate the service life of waterborne maskant such that suppliers and users could perform adequate testing to evaluate long term performance of waterborne chem-mill maskant.

Historic records indicate waterborne chem-mill maskants were evaluated, developed, and considered for implementation at a few chemical milling operations in the late 1970s, however, a perchloroethylene based maskant and solvent collection system was selected as the best process for compliance with the regulations enacted by some states. The primary concern with waterborne maskants during those initial evaluations was in-tank stability. Early waterborne maskant systems demonstrated sensitivity to mechanical forces exerted by the pumps used for material transfer and tank circulation.

In the late 1980s there was a renewed effort to develop and implement waterborne chem-mill maskants. The initial maskant formulations offered in the late 1980s were essentially the same products that did not work when evaluated ten years earlier. Hence the maskant stability question was again foremost in the minds of those considering implementation of waterborne maskants. The need for techniques for estimating the tank life of a maskant was apparent.

Immersion, or dip application of chem-mill maskant is the preferred coating technique for sheet metal parts with severe contours and extrusions. Immersion coating reduces maskant coating defects, eliminates difficulties with spray or flow coating equipment and spray booth maintenance. Along with equipment development activities,^[7] a series of equations was derived to describe the service life of maskant in an immersion coating system. Mixing studies were conducted to determine the tank life of waterborne maskants. Tank designs, maskant operating temperatures, pH and impeller configurations were tested (Table 2). The time base for each test run was determined with Eqs. (1)–(4). Mixing study research demonstrated that water-borne maskant stability concerns are essentially unfounded, provided process control recommendations for maskant maintenance are adopted as standard practice.

Maskant tank life calculations are based the observation that new, or fresh maskant is added to an immersion coating system, then thoroughly mixed with maskant resident in the tank (Fig. 13). Assume a 200 gal/day mask usage, and a total tank volume of 6000 gal. This relation can be modified and written in the form of the “Law of Natural Decay”.^[9] The new expression is:

$$G_r = C_{ekt} = 6000e^{kt} \quad (1)$$

Table 2 Mixing study test plan example

Factors	(–)	Levels units	(+)
A Impeller Tip Speed	4	ft/sec	15
B Impeller Type	100	Model #	310
C Maskant pH	low		high
D Maskant Temperature.	80	°F	150

Fig. 13 Immersion tank operating schematic

where

G_r = Gallons of original mask remaining

C = Constant tank volume, 6000 gallons for current tank

t = time, days

k = Coefficient of mask usage = $-3.39 \times 10^{-2} \text{ day}^{-1}$, for 200 gal/day mask usage

The linear plot of $G_r = 6000 e^{kt}$ for $k = -3.39 \times 10^{-2}$ (Fig. 14).

The new expression provides an accurate estimate of the volume of the original tank charge of maskant remaining in the tank at any time (t). However, values for G_r are valid only if maskant added to maintain tank volume is sufficiently mixed with resident maskant to produce a homogeneous mixture.

Impeller (or propeller) type mixing apparatus may be used to promote homogeneity of newly added and resident maskant. When placed in a draft tube apparatus mixers become inefficient pumps capable of moving large volumes at low pressure. Mechanical pumps are more effective for moving low volumes at high pressure. Hence, mechanical pumps are less effective for mixing/blending large tank volumes. Also, proper placement of mixing impellers produce tank surface flow conditions conducive to good quality mask coatings. Therefore, a new unit is introduced,

Impeller Cycles (C_i). Impeller Cycles shall be defined as the number of times the tank volume passes through a mixing impeller per unit time. Impeller Cycles can be simply defined as the quotient of the total pumping capacity of the mixing impellers used in the tank, and the tank volume.

C_1 = Average number of impeller cycles occurring each day

where

C_1 = total pumping capacity (gal/day)/tank volume (gal/cycle)

C_i = Cycles/day

C_1 describes the rate at which the tank contents passes through the mixing impellers. However, as described per Eq. 1, the volume of the original tank charge diminishes relative to time. The original tank charge is blended with new mask and the mixture is applied to parts immersed in the maskant. Therefore, the impeller cycles experienced by the original tank charge also diminish relative to time. The diminishing impeller cycle rate is (I_c), and is defined as

$$I_c = C_1 e^{kt} \quad (2)$$

Fig. 14 Mask tank original charge versus time

where

I_c = Impeller Cycles, rate for original tank charge at any time (t), cycles/day

C_1 = Average number of impeller cycles occurring each day, for the entire tank volume, cycles/day

t = time, days

k = coefficient of mask usage, day⁻¹

Perhaps more useful information would be an estimate of the total number of impeller cycles to which a maskant is subjected from the time of mixer activation, ($t = 0$), to any time (t). The following equation provides a numerical estimate of the total number of impeller cycles (I_{ct}), at any time (t):

$$I_{ct} = C_1(e^{kt} - 1) / k \quad (3)$$

where I_{ct} = Impeller Cycles, total

Equation 3 is derived from Eq. 2, reference Appendix A.

The total number of impeller cycles to which a maskant will be subjected to during its entire tank life is:

$$I_{cm} = -C_1 / k \quad (4)$$

where I_{cm} = Impeller Cycles, maximum

Reference Appendix A.

Substitution of different constants and mask usage coefficient allows the equations to be used to model mask tank operations of any magnitude. For example, a manufacturer uses a particular maskant product that covers 650 ft² at 1.0 mils (1 mil = 0.001 in.) coating thickness. Parts immersed in the maskant actually receive a nominal coating thickness of 6.5 mils. The manufacturer has a 2000 gal capacity maskant tank and coats 500,000 ft² of substrate each year.

Maskant usage per year:

$$(650 \text{ ft}^2 / \text{gal}) / 6.5 \text{ mils} = 100 \text{ ft}^2 / \text{gal} \text{ actually surface coverage.}$$

$$\begin{aligned} (500,000 \text{ ft}^2) / 100 \text{ ft}^2 / \text{gal} \\ = 5000 \text{ gal of maskant per year, minimum usage.} \end{aligned}$$

Maskant time in tank: the manufacturer operates a 2000 gal tank, 16 hr per day, 250 days per year. The average maskant usage per day is:

$$(5000 \text{ gal mask/yr}) / 250 \text{ mfg. days/yr} = 20 \text{ gal mask/day.}$$

Equation 1 can be rearranged was follows:

$$\begin{aligned} G_t &= 2000e^{kt} \\ K &= \ln[(2000 - 20)/2000] = -1.005 \times 10^{-2} \end{aligned}$$

The mask tank used by the manufacturer has six (6) mixing impellers with a pumping capacity of 2500 gal/min. The mixers are operated intermittently. Total mixer operation time is 8 min each hr, or 128 min each day. Impeller Cycles per day (average):

$$\begin{aligned} (2500)(8)(16) [\text{gal} \cdot \text{min} \cdot \text{hr} / \text{min} \cdot \text{hr} \cdot \text{day}] &= 320,000 \text{ gal/day} \\ \Rightarrow C_1 &= (320,000) / 2000 [\text{gal} \cdot \text{cycle} / \text{day} \cdot \text{gal}] \\ &= \mathbf{160 \text{ Impeller Cycles/day.}} \end{aligned}$$

Thus, Eq. 4 becomes:

$$I_{ct} = 160(e^{kt} - 1) / k.$$

Providing the total number of impeller cycles at any time (t).

The maximum number of impeller cycles experienced by the original tank charge of maskant during time in tank is:

$$I_{cm} = -160 / (-1.005) \times 10^{-2} = \mathbf{15,920 \text{ Impeller Cycles}}$$

The test apparatus for such a system would consist of a small scale tank (10 gal with mixer(s) and draft tube(s). A pump could also be used if such a tank design is desired. Assuming that mixers are selected a test plan is developed to compare the additive effects of impeller selection, impeller tip speed, maskant pH control and maskant operating temperature (Ref. Table 2). Based on the estimations from Eqs. 1–4, each test run should last 15,160 Impeller Cycles.

The advantage provided by the equations allowed for rapid evaluations of equipment designs and maskant formulae while modeling the expected tank life of waterborne maskant products. Derivation of the equations appears in the Appendix A as they are also applicable for other processes that employ emulsions and immersion tanks, e.g. electroprime painting.

Waterborne Maskant Chemistry

In addition to the stability issue, some waterborne maskant product offerings in the 1980s consisted of multiple coatings and cure cycles. A maskant product promoted by the DeSoto Aerospace Coatings Co., consisted of three separate coatings, (applied by immersion or spray), with a cure cycle for each. Although complicated, the products produced very good results. Unfortunately, the product was considered too complicated by most potential users for practical use.

Competition among maskant suppliers resulted in much improved masking systems with stable chemistry and simple control techniques. Actual waterborne maskant chemistries are proprietary formulas protected by the maskant suppliers. Waterborne maskant offerings now provide performance attributes equal to, and in some categories,

exceeding the present capabilities of solvent based maskants. Waterborne maskants as applied have higher volume solids, which equates to covering more surface area per gallon of maskant.

Waterborne Maskant Limitations

Waterborne maskants may not be used in process lines that serve to prepare parts for bonding. Surfactants inherent in waterborne maskant systems will leach into processing solutions, and influence the surface tension of anodize solutions. However, no bond adhesion test specimens processed with a surfactant “contaminated” anodize solution are reported to have failed acceptance testing.

Waterborne maskants currently available will not perform well following autoclave cycles. In metal bonding applications a bond cycle of 8–10 hr at 250–350°F exceeds the capabilities of waterborne maskants. The long cure time at high temperature over-cures maskant resulting in excessive adhesion. A waterborne maskant could be developed for such an application, but there have been no development attempts to date.

Regulatory Requirements

The viable compliance approaches are reduced to use of a waterborne maskant, use of a maskant with a compliant solvent diluent, or use of standard solvent-based maskant with solvent emission abatement equipment. In some regulatory environments, emissions compliance with abatement equipment triggers additional record keeping requirements to insure verification of meeting a required emission capture efficiency*.

There are essentially three options for use of solvent-based masking systems while remaining compliant with most solvent emission limits.

- Use solvent-based maskant in conjunction with solvent abatement equipment.
- Use a compliant solvent such as Oxsol-100.
- Purchase the maskant as a concentrate such that the solvent content is 622 g/l, then cut the maskant to operating viscosity with a compliant solvent (applicable for Type I etchant users only).

In all cases the user must insure that the compliance technique and application process does not exceed the worker exposure limits (i.e. OSHA Personal Exposure Limit (PEL) in USA) for the solvent(s) selected. In addition the user must be certain that solvents selected comply with all local regulations and that all equipment used near masking

areas where flammable solvents are used comply with local fire codes.[†]

Solvent-based maskants with abatement equipment allows two options.

- Use a flammable solvent diluent such as toluene, acetone, xylene or Oxsol-100 with thermal oxidation equipment. Solvent emissions are burned and the heat of combustion can be captured for use elsewhere in the facility. All equipment near the masking operation must be explosion proof and when the solvent load from the masking operation drops before a prescribed minimum, natural gas or other fuel must be used maintain proper combustion temperature.
- Use a chlorinated solvent such as perchloroethylene and Carbon Bed Solvent Collection.

Perchloroethylene with carbon bed solvent collection is perhaps the best choice if solvent-based masking operations are preferred. Carbon beds can tolerate low solvent loading and remain relatively efficient. Properly designed carbon bed systems can maintain 95–98% collection efficiency of all solvent that enters the inlet plenum, (Figs. 15 and 16).

Once a collection bed is completely loaded, steam is injected into the bed to strip the solvent. The mixture of solvent and steam is piped to a condensing section. From the condenser the mixture is piped to a water separation tank. Solvent is piped to a storage tank for reuse, and water is routed to an industrial sewer, or water-solvent stripping device to assure that no solvent enters the sewer system. The collected solvent may be returned to the maskant supplier and used in new maskant, and used to dilute incoming maskant concentrate. For abatement equipment 81% capture efficiency is required per the Aerospace NESHAP[‡]. A capture efficiency of 81% equates to a solvent emission of approximately 236 g/l (grams of solvent emitted/liter of maskant applied) depending on the solvent-based maskant used. To operate within prescribed emission limits solvent emissions must be prevented before the solvent laden reaches the abatement equipment (Ref. Fig. 16).

A gross comparison of three frequently used compliance techniques appears in Table 3.

Record Keeping Requirements^[7]

Following initial compliance demonstration/verification, operators of thermal oxidation systems must retain daily records of exhaust stack emissions and equipment operation parameters. All instrumentation must be operational while the oxidation equipment is operating.

Operators of carbon bed solvent collection equipment must maintain a daily material balance to and report

*In the USA Aerospace NESHAP (National Emissions Standard for Hazardous Air Pollutants) derived from the 1990 Clean Air Act require 81% capture efficiency for solvent emission abatement equipment.

[†]Oxsol-100 is a flammable solvent as is Toluene. Perchloroethylene is not flammable and can be used with solvent emission abatement equipment.

[‡]Applicable in the USA.

Fig. 15 Primary elements of carbon bed solvent collection

Fig. 16 Operation schematic for solvent emission abatement

emissions for a 7–30 day rolling average to demonstrate 81% capture. The material balance is an accounting of all solvent that entered the maskant system with all solvent collected by the solvent collection system. The difference is the solvent emission. The material balance is based on information from flow totalizers that measure the volume of solvent transferred from the solvent bulk storage tank to the maskant tank, and solvent collected and transferred to the bulk storage tank (Fig. 17). An example of a material balance performed on an operation carbon bed solvent collection system appears in Table 4.

Material Balance Summary, reference Table 4:

- **Maskant Inventory:** Maskant is conveniently received in totes of 250–400 gal capacity. Drums (55 gal) may be used also, but increased handling labor is incurred. A flow meter or flow totalizer could be used, however maskant concentrate viscosity of 22–24 Poise as
- received, compounded with higher viscosity in cold weather and entrained air (from tote changes), etc. make accurate flow measure difficult.
- 1185Maskant may be purchased as a concentrate to reduce shipping costs. Recovered solvent is used to dilute the maskant to operating viscosity (18–20 Poise). The volume of solvent can be metered from the bulk tank (Fig. 17). An alternate arrangement would be to pump mask concentrate directly to the mask tank, then increase solvent additions for viscosity control.
- Maskant Viscosity is controlled with solvent pumped directly into the maskant tank.
- Solvent in bulk storage is solvent collected and stored for reuse in the maskant system, or pumped to empty maskant totes for resale to the maskant supplier.
- Solvent added for system replenishment is any solvent added to the system from an outside source.

Table 3 Maskant compliance approach

Flammable Solvent Diluent with Thermal Oxidation	Chlorinated Solvent with Carbon Bed Solvent Collection Equipment	Waterborne Chem-Mill Maskant
Allowed Emission: 81% Capture Reporting Frequency: 7–30 day Rolling Average (Site Specific)	Allowed Emission: 81% Capture Reporting Frequency: 7–30 day Rolling Average (Site Specific).	Allowed Emission: 160 g/l Report Frequency: none
Advantages: Low cost maskant Low cost abatement equipment Waste heat from combustion can be reclaimed for use	Advantages: Low cost maskant relative to water-borne maskants or compliant solvent alternatives. Non-flammable Collected solvent can be reused for cutting mask concentrate or making new maskant	Advantages: Compliant – no record keeping requirements Improved abrasion and pull-up resistance.
Disadvantages: 24 hr/day stack emissions and equipment monitoring. Ongoing record keeping requirements for local and federal regulatory agencies	Disadvantages: Daily material balance Ongoing recording keeping requirements for local and federal regulatory agencies	Disadvantages: Higher maskant adhesion to substrate, (if solvent-based maskant adhesion is 12–14 oz/in., waterborne borne maskant adhesion will be 20–25 oz/in.
Equipment maintenance Mask line downtime during equipment maintenance and emergency repairs Introduction of any chlorinated solvent carries the risk of severe corrosion potential Flammable solvent use increases insurance premiums and necessitates use of explosion proof equipment. Limited service life.	Equipment maintenance Mask line downtime during equipment maintenance and emergency repairs Corrosion – chlorinated solvents will evolve small amounts of hydrochloric acid, which will corrode equipment components and eventually the carbon bed vessels. Limited service life—10–15 years.	
Cost Estimate: Asymptotic to both <i>X</i> and <i>Y</i> Axes as abatement equipment costs remain fixed, i.e. y (\$/sq ft) = Fixed \$/Area Coated.	Cost Estimate: Asymptotic to both <i>X</i> and <i>Y</i> Axes as abatement equipment costs remain fixed, i.e. y (\$/sq ft) = Fixed \$/Area Coated.	Cost Estimate: Asymptotic to both <i>X</i> and <i>Y</i> Axes as abatement equipment costs remain fixed, i.e. y (\$/sq ft) = Fixed \$/Area Coated.
Plan for equipment replacement at or about the end of the capital equipment depreciation periods	Plan for equipment replacement at or about the end of the capital equipment depreciation periods	Cost estimate function is essentially linear beyond capital equipment depreciation period as maskant and operating costs track with usage

For example, if the bulk storage tank is low, new solvent may be purchased in 55-gal drums and the contents of said drums pumped directly into the mask tank. If no new solvent is added to the bulk storage tank then the entry for Solvent Added is zero (0).

- Solvent for Resale is recovered solvent excess to system needs. The solvent is pumped to empty maskant totes and returned to the maskant supplier where it is used in the manufacture of new maskant.
- Solvent Removals are quantities of solvent workers remove from the system for other purposes. For example, the solvent may be used to dissolve maskant from mask line hang hooks. Solvent used for such purposes, i.e. recovered solvent now containing a small amount of maskant solids should be added directly to the maskant tank, and an entry made for Solvent Added to System.
- Recovery efficiency is the quotient of Total Solvent Recovered and Total Solvent Added. The Uncertainty associated with Recovery Efficiency results from measure error propagation. Error propagation is

additive and for solvent emissions, which is the quotient of Solvent Recovered and Solvent Added to System error is:

$$\delta \text{ Emission/Emission} = (\delta \text{ Solv. Recovery/Solv. Recovered}) + (\delta \text{ Solv. Add/Solv. Added}). \quad (5)$$

As indicated by the Material Balance, solvent collection efficiency must be a minimum of 81% to meet regulatory requirements. To assure compliance, collection efficiency must be maintained at 83%. Pitfalls with solvent collection and the material balance is equipment maintenance and control of solvent removals and additions. A valve failure on a carbon bed, if not repaired in a timely manner, will result in non-compliance. Workers removing or adding solvent without recording the activity, and volumes of solvent transferred, will greatly skew the material balance. To be successful as a compliance approach, carbon bed solvent collection and material balance reporting requires timely equipment maintenance and careful material control.

Fig. 17 Solvent abatement material balance

Estimating Costs for Masking Systems

The cost estimating technique presented for all compliance approaches are based on an exhaustive accounting of solvent-based and waterborne masking systems. The cost estimate were developed by aerospace airframe manufacturer as a means of comparing the relative costs of three techniques for complying with Aerospace NESHAP emission limits in the USA. The cost estimate results are presented here to demonstrate the unit cost of coating aluminum with chem-mill maskant and how solvent abatement equipment can be prohibitively expensive if work load falls below the economic threshold. Cost estimates are based on 1997 dollars and include equipment costs, maintenance and operating costs for the particular control device and support costs for safety and environmental issues. Items not included are equipment installation costs, or costs for material handling and automated conveyance equipment as such costs are site specific.

Calculating Maskant Surface Coverage and Estimating Maskant Use Maskant suppliers will report the solids content of a maskant as % by weight, and sometimes they will include solids content as % by volume. To determine the area that a maskant will cover, solids as % by weight must be converted to solids as % by volume. The unit used to describe coating coverage is $\text{ft}^2\text{-mil/gall}$, i.e. the area covered by 1 gall of maskant, with a dry coating thickness of 1 mil (0.001 in.). Calculating the actual coverage

for a particular maskant is important as suppliers offering a lower price may simply be diluting their product and selling more water or solvent, whatever the situation may be. See Appendix B for surface coverage calculation technique.

Thermal Oxidation Thermal oxidation equipment for flammable solvent is generally the least expensive abatement equipment. The function describing the unit cost of operating thermal oxidation equipment is the quotient of capital cost of the abatement equipment (depreciated over 13 years), plus recurring costs for maskant and abatement equipment, and the total area of aluminum to be coated at an idea maskant film thickness. It is reasonable to assume a service life for thermal oxidation equipment is equal to the depreciation period. Hence, once the depreciation period ends, the equipment will be replaced with like equipment (Fig. 18).

$$\$/\text{ft}^2 = (\$63,000 + \text{Recurring Costs})/\text{Surface Area.} \quad (6)$$

Where Recurring costs are all maintenance and equipment utility costs and maskant costs. Solvent-based maskants will cover approximately 28 ft^2 with a dry mask film, 14–15 mil thickness.

Carbon Bed Solvent Collection Carbon Bed Solvent Collection of non-flammable solvent such as perchloroethylene is a good compliance choice for varying solvent

loads. The function describing the unit cost of operating carbon bed solvent collection equipment is the quotient of capital cost of the abatement equipment (depreciated over 13 years), plus recurring costs for maskant and abatement equipment, and the total area of aluminum to be coated at an idea maskant film thickness. It has been demonstrated that service life of carbon bed solvent collection equipment is equal to the depreciation period. Hence, once the depreciation period ends, the equipment will be replaced with like equipment (Fig. 19).

$$$/ft^2 = (\$53,000 + \text{Recurring Costs}) / \text{Surface Area} \quad (7)$$

Waterborne Maskant Waterborne maskant requires the lowest capital expenditure and the lowest costs for maintenance. Unlike abatement equipment, waterborne maskant will become less expensive when the depreciation period ends (Fig. 20).

$$$/ft^2 = (\$45,000 + \text{Recurring Costs}) / \text{Surface Area} \quad (8)$$

Waterborne maskants will cover approximately 29 ft² with a dry mask film, 18–20 mil thickness. Waterborne maskants will cover more surface area with greater film thickness due to higher volume solids content of the liquid maskant. Typical weight solids for solvent-based maskant is 20 wt% and 25 vol% and the product is used at viscosity of 18–22 Poise. Waterborne maskant are typically 42–45 wt% and 30–40 vol% and are applied at viscosity of 25–40 Poise. In the out-years following the capital equipment depreciation period the unit cost function is (Fig. 21).

$$$/ft^2 = (\$700 + \text{Recurring Costs}) / \text{Surface Area} \quad (9)$$

Taguchi Loss Function as Cost Estimating Technique
An unconventional cost estimating technique that is

Fig. 19 Carbon bed solvent collection, \$/sqft versus area coated

Fig. 20 Waterborne maskant, \$/sqft versus area coated

Fig. 21 Waterborne maskant, \$/sq ft versus area coated

valuable for all projects with an environmental impact, i.e. any manufacturing process regulated by a government agency, is the Taguchi Loss Function.^[10] The traditional view of environmental compliance is simply reducing emissions to fall within compliance bounds. Hence, if an emission limit is 160 g/l, then compliance is achieved if emissions are controlled to 159 g/l.

The Taguchi Loss Function ranks processes, or a compliance approach by the overall impact on society. By Taguchi's logic a violator starts paying a debt to society when emission limits are exceeded, however society still pays for health disorders even at emission levels somewhat lower than the limit defined by law. Hence, emitting 159 g/l, though legal, really is not any better in terms of environmental improvement than emitting 161 g/l, which would trigger a fine.

In the case of environmental issues the loss to society is the cost paid to treat cancer, respiratory disorders, and other health issues. The loss to a company is in the form of

finest paid to regulatory agencies, and increased health and operating insurance premiums. Taguchi's Loss Function

$$\text{\$ Loss} = kx^2 \quad (10)$$

where

\$ Loss is the loss to society due to poor air quality, e.g. ozone alert days:

x is solvent emissions from a chem-mill masking operation

$$\text{let } x = \sigma + \mu$$

where

σ is the Standard Deviation of solvent emissions from abatement equipment, and μ is the average emission from solvent abatement equipment.

$$\Rightarrow \text{\$ Loss} = k[\sigma^2 + \mu^2] \quad (11)$$

Industry example—a “Case Study” of statistical methods for cost comparison. First calculate probabilities of exceeded allowed emission limits, then compare Taguchi Loss Function.

Solvent Abatement—a 10,000 CFM Carbon Bed Solvent Collection system operated for 13 years capturing solvent emission from a chem-mill masking operation at a large aerospace company. Operating history indicated average emission (μ) to atmosphere from the system was 120 grams solvent per liter of maskant applied, with Standard Deviation $\sigma = 74$ g/l. Emission limits allowed per the Aero-space NESHAP, effective September 1998, are 160 g/l for Type II etching (for compliant maskants), 236 g/l for Type II etching (for solvent abatement equipment), and 622 g/l for Type I etching.

The probability of exceeded the mandated emission limits can be estimated based on the long-term performance of the system described. It should be noted that maintenance of the system described was not a priority. This fact is evident in the standard deviation of solvent emissions for the system.

With the solvent collection system operating as described, the probability of a compliance failure based on the equipment operating history and the 236 g/l limit may be calculated.^[11] It is assumed that solvent emissions from the described system are normally distributed with mean emissions of $\mu = 120$ g/l and standard deviation $\sigma = 74$ g/l, i.e. $x \sim N(\mu, \sigma^2)$, or $x \sim N(120, 74^2)$. A process drift of 1.5σ is included,^[12] i.e. $(1.5)(74) = 111$ g/l.

$$P\{x \geq \alpha\} = 1 - P\{z \leq (\alpha - \mu)/\sigma\} = 1 - \Phi[(\alpha - \mu)/\sigma] \quad (12)$$

Where $\Phi(\bullet)$ is the cumulative distribution function of the standard normal distribution (mean = 0, standard deviation = 1).^[11]

Then, from Eq. 11

$$\begin{aligned} P\{x \geq 236\} &= 1 - P\{z \leq (236 - 120)/111\} \\ &= 1 - \Phi[(\alpha - \mu)/\sigma] \\ &= 1 - P\{z \geq 1.0450\} \\ &= 1 - \Phi(1.0450) \\ &= 1 - 0.85199 \text{ (table value)} = 0.15, \text{ or } 15\% \end{aligned}$$

Based on the historical data, that particular solvent collection system would be out of compliance 15 days out of 100.

Assume that the latest in solvent collection equipment, plus careful maintenance, can reduce both average solvent emissions and emissions variance such that $\mu = 110$ g/l and $\sigma = 40$ g/l; $1.5\sigma = 60$ g/l. The probability of compliance failure and fines becomes

$$\begin{aligned} P\{x \geq 236\} &= 1 - P\{z \leq (236 - 110)/60\} \\ &= 1 - P\{z \leq 2.1\} \\ &= 1 - \Phi(2.4) \\ &= 1 - 0.98422 \text{ (table value)} = 0.016, \text{ or } 1.6\% \end{aligned}$$

Thus, unless equipment maintenance remains a high priority, the solvent collection system could slip out of compliance 15 days for every 100 days. At \$22,000/day the potential annual fine is approximately \$818,400 (Fig. 22).

In contrast, a waterborne system is available at lower capital cost that contains 36 g/l of a VOC and solvent content standard deviation is $\sigma = 3$ g/l. The probability of non-compliance with the 1.5σ process drift is

$$\begin{aligned} P\{x \geq 160\} &= 1 - P\{z \leq (160 - 36) / 4.5\} \\ &= 1 - P\{z \leq 27.556\} \\ &= 1 - \Phi(27.556) \\ &= 1 - 1.0 \text{ (table value)} = 0.0, \text{ or no chance.} \end{aligned}$$

Thus, the potential annual fine for a waterborne masking system is \$0. Assume that the maskant supplier, or the

Fig. 22 Taguchi loss function

resin supplier mistakenly creates a batch of maskant with 50 g/l VOC or HAP

$$\begin{aligned} P\{x \geq 160\} &= 1 - P\{z \leq (160 - 50)/4.5\} \\ &= 1 - P\{z \leq 24.4444\} \\ &= 1 - \Phi(24.4444) \\ &= 1 - 1.0 \text{ (table value)} = 0.0, \text{ or no chance.} \end{aligned}$$

A Taguchi Loss Function example can be developed from the information provided. The federal fine for exceeding emission limits is \$22,000/day for each day of non-compliance. Then rearrange Eq. 11

$$k = \$22,000 / [(74)^2 + (120)^2] = 1.11$$

The theoretical loss to society, for the best solvent collection system is

$$\text{\$Loss} = 1.11[(60)^2 + (110)^2] = \$17,427/\text{day}$$

The theoretical loss to society for a competing waterborne maskant, relative to the solvent collection system becomes

$$\text{\$Loss} = 1.11[(4.5)^2 + (36)^2] = \$1,461/\text{day}.$$

Where possible, the compliant maskant system is a better choice. New zero VOC waterborne maskants will enter the market in 1999, reducing the loss to society to \$0.

TOOLING

Tools for chemical milling may consist of a simple scribing template, or may be a group of tools and sample pieces consisting of a Drill Template, Chem-Mill Template, Router Block, Sample Part #1 and Sample Part #2.

A typical sheet metal fabrication process includes forming, heat treat and age followed by chemical milling, chemical processing and paint. A Drill Template is applied to the formed part after heat treat and age. The Drill Template locates the reference holes (tooling holes) necessary for proper location of the Chem-Mill Template and the Router Block*. The Chem-Mill Template is located on the part contour with tooling pins that are inserted into the holes located by the Drill Template. After Chemical Milling, the Router Block is located on the part contour by pinning the Router Block into the holes located by the Drill Template. Sample Part #1 is a reference part that is formed to contour and has notations of all final part features engraved in the part surface. Sample Part #2 is a reference part that has been produced with the Drill Template, Chem-Mill Template and Router Block and inspected to confirm that part produced by the tools conform to blueprint requirements.

Tooling materials are dictated by part fabrication requirements. Flat parts can be produced with tools fabricated from fiberglass or sheet metal (aluminum or steel). Sheet metal tools are typically used when the part to be fabricated is flat. The tools can be cut on a laser or water-jet machine at minimal labor cost. Flat tool fabrication is a relatively simple matter if the chem-mill geometry is available in electronic form. Fiberglass tools may also be used for flat parts, but tool fabrication cost is somewhat higher. The advantage of fiberglass as a tool material is that the tool can be easily modified. Metal tools are typically scrapped and replaced. In general, sheet metal is used as fabrication tools for flat parts, and fiberglass is used as fabrication tools for parts with contour.

The location and geometry for chemically milled features are generally transferred from a master model of the part in a lofting[†] operation, however loft data in electronic form will greatly accelerate the process.

Chem-mill Templates are used to locate the scribe line relative to some reference point. An important distinction here is that the scribe tool defines the Chem-Mill Scribe Line, or Chem-Mill Template Line (CMTL). After etching, the Chem-Mill Line (CML) remains. It is the chem-mill line that must be located correctly relative to a reference point (Fig. 23).

Tool-makers must accommodate two phenomenon know as Chem-Mill Undercut, and Chem-Mill Set-Back (Fig. 24). Undercut is analogous to the cutter offsets employed by programmers of numerical control machines. Set-Back is unique to chemical milling.

Chem-Mill Undercut and Undercut Ratio

Chemical etchants etch beneath the maskant, parallel to the substrate surface simultaneously with the etching action normal to the substrate surface. The rate of simultaneous etching parallel and normal to the substrate surface usually is not equivalent (Ref. Fig. 23). Chem-Mill Undercut is typically defined as a ratio such that the tool-maker need only multiply the undercut ratio by the depth of cut to calculate the necessary tool offset.

Design Engineers may require that some chemically milled features are located accurately. For example, chemical milling may be used to create a recessed area for an overlapping part (Figs. 25–27), or to create boss areas for fasteners or bulkhead pass-through holes (Fig. 28). Land areas located between chemically milled pockets must be very close to the target dimension to insure proper edge distance for rivet holes. For example, a tool-maker must construct a chem-mill template that will produce a chem-mill line located 1 in. from two reference points (Figs. 25 and 26); chem-mill

*When possible the Drill Template and Routing Functions are combined into one tool.

[†]In ship building a loft is constructed above the keel and hull surface points are scaled off a model of the hull and transferred via plumb lines and levels and measuring instruments to define points on the hull surface.

Fig. 23 Chem-mill undercut ratio, or etch factor

Fig. 24 Chem-mill set-back

Fig. 25 Chem-mill pocket recess

Fig. 26 Chem-mill pocket recess, right reference point

Fig. 27 Chem-mill pocket

Fig. 28 Chem-mill land

pocket (Fig. 27) 2.0 in. wide, and in an adjacent part area a 2.0 in. wide chem-mill land (Fig. 28). The Undercut Ratio, or Etch Factor for the material is 1.5, and the depth of cut is 0.070 in.

- Tool Dimension for Line, Left Ref. Point (Fig. 25):
 $1 - (0.070)(1.5) = 0.9$ in. from reference point, i.e. CMTL must be 0.9 in. from reference to produce CML 1.0 in. from reference.
- Tool Dimension for Line, Right Ref. Point (Fig. 26):

$$1 + (0.070)(1.5) = 1.11 \text{ in.}$$

- Tool Dimension for the Pocket:

$$2 - (2)(0.070)(1.5) = 1.79 \text{ in.}$$

- Tool Dimension for the Land:

$$2 + (2)(0.070)(1.5) = 2.21 \text{ in.}$$

Chemically milled features that do not meet the target, or nominal, blueprint dimensions could make the part heavier than necessary, and could perhaps create a geometrical stress riser that could cause premature fatigue failure.

Chem-Mill Set-Back

Chem-Mill Set-Back applies to multi-cut parts only. Chem-Mill Set-Back occurs between joining pockets of different cut depths. Once maskant is removed from an area adjacent to a previous cut, etching occurs on all surfaces (Fig. 24). The initial chem-mill line will move relative to a fixed reference point, but not as far as undercut. The accepted rule of thumb is that set-back is $1/3$ of the depth of cut for the remaining pocket, however this heuristic is not entirely correct. Chemical milling is area sensitive. If the initial or previous cut is shallow (20 mils or less), there will be little or no set-back. If the initial cut depth is 50% of the joining cut, set-back is the multiple of 0.8 and the depth of the joining cut. If the initial cut depth is 100% of the joining cut the set-back is the multiple of 1.2 and the depth of the joining cut. Assume a tool-maker must construct a tool that will locate the first cut CML 1 in. from the reference point, and the Cut 2 CML 2 in. from the reference point (Fig. 24). The undercut ratio for the material is 1.0; Cut 1 depth is 60 mm, Cut 2 depth is 70 mm, and the ratio is ~ 1.0 . Then the CMTLs must be located accordingly:

- CMTL Cut 2: $2 - (0.07)(1.0) = 1.93$ in. from reference
- CMTL Cut 1: $1 - (0.06)(1.0) - (0.07)(1.2) = 0.86$ in. from reference.

Area Rules in Chemical Milling

Chemical milling is a convenient manufacturing technique for reducing the weight of complex sheet metal forms. Without chemical milling, aircraft such as the North American XB-70 Valkyrie or Boeing's 747 would have been more difficult to fabricate, and perhaps hopelessly overweight. As a weight reduction technique, designers tend to position chem-mill pockets in every available space without regard to pocket size. Unfortunately, large variations in pocket sizes will result in large variations in finished pocket depth (Fig. 29).

For example, if a pocket of approximately 2 in² area is adjacent to a 48 in² pocket and both pockets are the same cut, the finished dimensions will differ by as much as 10 mils. Therefore, a relevant design heuristic is to minimize variation of pocket size for a particular cut, e.g. no pocket within a particular cut number should have area twice as great as any other pocket. Also, part designers should minimize the number of cuts while maximizing the cut depths. This heuristic will serve to limit finished dimension variations to approximately 4 mils, reduce finished part weight and simplify all tooling (Fig. 30).

Calculating Cut Removals

In addition to calculating undercut offsets, set-backs and sizing scribing templates according, tool-makers must also determine the actual removals for each chem-mill cuts. Part blueprints will show the finished dimension for each pocket, i.e. the final thickness of each chemically milled pocket for a complete part. The finish dimensions must

Fig. 29 Chem-mill pocket differential

Fig. 30 Pocket change order to correct pocket depth differential

Fig. 31 Cut removal calculations, 4-Cut part

Table 5 Removal calculation, 4-cut part (Fig. 31)

Cut	Stock thickness (mil)	Finish dimension (mil)	Delta	Double cut	Delta— previous cuts	Removal (mil)
4	100	71	29			29
3		60	40		40 – 29	11
2		45	55		55 – 29 – 11	15
1		32	68		68 – 29 – 11 – 15	13
Check cut	Stock thickness (mil)	Removals	Finish dimension (mil)			
1	100	13 + 15 + 11 + 29	32			
2		15 + 11 + 29	45			
3		11 + 29	60			
4		29	71			

be converted into removals for the chem-mill operator (Fig. 31). Finish dimensions are converted to removals for a simple multi-cut part (Table 5).

Chemical milling simultaneously from multiple surfaces, or Double Cut, requires special considerations (Fig. 32). Finish dimensions are converted to removals for a simple multi-cut part with removals from opposing surfaces (Table 6).

Double cut areas will eventually confuse both tool-makers and chem-mill operators. The problem is inconsistency in part dimensioning practice. Part dimensions on the blueprint may appear relative to either the substrate stock thickness, or relative to the finish dimension in the double cut area. The tool-maker must pay close attention to the finish dimensions and their locations relative to other cuts on the opposite side of the part. For example, if the

Fig. 32 Double cut

Table 6 Removal calculation, double cut (Fig. 32)

Cut	Stock thickness (mil)	Finish dimension (mil)	Delta	Double cut	Delta—previous cuts	Removal (mil)
2	160	40	120	yes	120 – 2(40)	40
1		80	80		80 – 40	40
Check cut	Stock thickness (mil)	Removals	Finish dimension (mil)			
1	160	40 + 40	80			
2		40 + 40	40			

Fig. 33 Double cuts and dimensioning practice

part designer had instead indicated a finish dimension of 105 mils for Cut # 6, and a finish dimension of 140 for Cut # 5, (Fig. 33) then all cuts are be calculated (Table 7 and 8).

ETCHANTS FOR ALUMINUM CHEMICAL MILLING

Aluminum is amphoteric, i.e. it is soluble in both acids and bases. Acid based aluminum etchants are used for aluminum cleaning operations, but seldom used for chemical milling operations. Acid etchants produce slow etch rates and leave a rough surface (Table 9).

The most widely used aluminum etchants are alkaline based with sodium hydroxide as the most popular alkali.^[1]

Aluminum etchant may consist of only sodium hydroxide and water, but most always include additives for improvement of surface finish, chem-mill radius, or fillet

and other process attributes. There have been no extensive studies to define the chemical mechanisms of etching, or metal dissolution, however the process is thought to be an electrochemical reaction similar to the accepted description of general corrosion.^[13] Hence, aluminum goes into solution at cathodic areas while anodic areas of the part emit electrons and reduce water to hydrogen and hydroxides. Current densities of 10×10^{-10} A/cm² have been measured.^[13] The cathodic and anodic surfaces must be approximately equal and moving rapidly about the part surface to produce an even etch. The generally accepted reaction in aluminum chemical milling is^[1]

As the aerospace industry began wide use of the chemical milling process there were a variety of solution formulae developed for various aluminum alloys

Table 7 Removal calculation, multi-cuts with double cut (Fig. 33)

(Table 10). As the process evolved the number of etchant formulae have been reduced to two general etchant formulas. For special applications and/or alloys various etchant constituents have been used^[14] (Table 11).

There are chemical milling operations that use only sodium hydroxide and water as an aluminum etchant. Such etchants produce a rough surface finish and may therefore be followed by a shot peening operation. It is left to the user to determine if savings in chemical costs justifies additional post-etch processing, and if their customer base would agree to such a process. Additions of scrap

aluminum and additives such as sodium polysulfide will improve process output. In general the industry has moved to create etchants that produce fine surface finishes, thus eliminating post-etch processes such as shot peening.

The wide variety of solutions has been reduced to two basic solution formulas that are applicable to virtually all aluminum alloys with little modification required. (Ref. Table 10)

Type I aluminum etchants have a cost advantage over the Type II etchant. Both etchant types are available as propriety formulas from chemical suppliers such as Turco

Products, Inc. The etchant supplier will provide general operating parameters to insure good process results (Fig. 34).

Additives such as sulfur, or sodium sulfide are included in the etchant formula to improve on chemical milling characteristics. Characteristics such as undercut, chem-mill fillet smoothness, surface finish and pocket dishing are all attributes directly related to the etchant. Sulfur, or a form of sulfur is added to both Type I and Type II etchant

**Fig. 34** Typical graph of optimum etchant chemistry ranges

to promote good surface finish. The sulfur precipitates zinc and copper alloying elements from solution and prevents the metals from plating back onto the substrate aluminum substrate surface, a phenomenon known as secondary masking. Triethanolamine, added to Type II etchants, is present to promote smooth fillets and to reduce/control chem-mill undercut. Ethylenediamine-tetraacetic acid (EDTA) is also a useful chelating agent that can influence chem-mill fillet quality.

Etchant operation typically proceeds from etchant make-up to eventual disposal of spent etchant. Aluminum etchants begin to produce poor surface finish and fillet quality as dissolved metal content reaches 60–70 g/l.

Control of the etchant is accomplished by simple titration. A sample of etchant is prepared and titrated with 1 Normal sulfuric acid. The first titration end-point is pH 11.3 (Fig. 35). The volume of titer represents that amount of free sodium hydroxide in solution, or N_1 . The second titration end-point is pH 8.2. The volume of titer needed to go from pH 11.3 to pH 8.2 represents the dissolved metal in solution, or N_2 .

Additions of sodium hydroxide, and decisions regarding the dump point of aluminum etchant is based on the titration results. Etchant N_1 and N_2 should be maintained as prescribed in the technical bulletin provided by the etchant supplier.

Addition of other etchant constituents is dependent upon how the etchant is operated. The traditional technique for Type II etchant, for example, is to operate the etchant until N_2 is in the range of 14–17, (or 60–75 g/l of dissolved aluminum), then dump the etchant and replace. All additives are added at etchant makeup and only water and sodium hydroxide are added thereafter. Other techniques include

Fig. 35 Etchant control

Fig. 36 Pocket defects

saving a portion of the spent etchant for the next etchant makeup to increase dissolved metal content in the new etchant. Regeneration of spent etchant to remove metals and recovery of sodium hydroxide and additives. In the latter techniques the user will follow analytical techniques supplied by the etchant supplier, or etchant regeneration equipment supplier to determine the timing and quantity if additive additions.

Spent etchant may convert from sodium aluminate to sodium hydroxide plus a mixture of aluminum hydroxide and aluminum oxide.^[1]

These reactions describe the mechanism by which sodium hydroxide can be recovered while separating the aluminum in solution. The process described by Eqs. (17) and (18) is used by aluminum manufacturers to purify bauxite.

There are undesirable effects of the chemical milling etchant chemistry (Fig. 36).

- Channeling is most often observed in titanium chemical milling, however if it occurs in aluminum chemical milling it is caused by part/pocket position during etching; low etchant temperature, or low N_1 .
- Overhang is caused by excessive triethanolamine concentration, or in some cases excessive dissolved metal in solution.
- Dishing results from excessive metal in solution, and excessive sodium hydroxide.
- Ridging in the fillet is caused in part by the orientation of the part during milling; hydrogen gas entrapment which can create flow-lines; poor desmutting practice*, or low N_1 .
- Rough, mottled, or “orange peel” surface is caused by “secondary masking”, or redeposition of zinc and copper alloying elements back onto the aluminum surface. Secondary masking occurs at low sulfur levels,

*For deep cuts (< 50mm), and for all 7000 Series Aluminium etch and desmutting after 10mm and desmutting for a few minutes will prevent ridging and pitting in the fillet.

and/or when N_2 reaches a range of 14–17 (in the absence of etchant regeneration).

- Fillet Notch is the result of excessive scribe knife pressure.

Complete reformulation of either Type I or Type II is seldom necessary. For a particular manufacturing situation, revision, or modification of an etchant may be necessary. Factorial design of experiment represents the best and quickest method for etchant development. Factorial designs are the correct choice by definition.^[15]

- “A factorial design experiment is arranged to study the effect on some observable quantity (the response) of varying two or more factors, such as process temperature and source of raw material. A series of values or levels of each factor is selected and certain combinations of the levels of all factors is tested. The objective of a factorial experiment is to measure the change in response when changing the level of some process factors while hold all other process factors constant. Such changes in the response are called the main effects of the factors and interaction effects between the factors.”
- “Definition of a Mixture Experiment—An experiment in which the response is assumed to depend only on the relative proportions of the ingredients present in the mixture, not the amount of the mixture. In a mixture experiment if the total amount is held constant and the value of the response changes when changes are made in the relative proportions of those ingredients that make up the mixture, then the behavior of the response is said to be a measure of the joint blending property of the ingredients of the mixture.”

In general etching operations, a volume of etchant is prepared, but is operated at varying volumes until analysis indicates an addition of sodium hydroxide or water is necessary. Therefore, a Factorial experiment design is appropriate for etchant formulation. Development of chem-mill maskants is a good example of a situation where a mixture experiment will provide the best experiment test plan. A typical test plant outline for etchant development (Fig. 37).

Waste Disposal

As the total dissolved metal content (N_2) reaches 14–17, or approximately 70 g/l, the quality of surface and fillet produced by the etchant will diminish rapidly (in the absence of etchant regeneration). Spent aluminum etchants can be handled in a variety of ways depending on the resources available.

Neutralization/Waste Haul Out

If an industrial waste-water treatment facility is on site, spent aluminum etchant can be neutralized and the

Factors	(-)	Levels Units	(+)

-	-	+	+			
+	-	+	-			
-	+	+	-			
+	+	+	+			

Fig. 37 Etchant development test plan

resulting sludge de-watered and hauled to landfill. This option is not entirely practical because mixing aluminum etchant with acid results in an extreme exothermic reaction, and hydrogen sulfide (H_2S) gas is a noticeable by-product. Use of neutralization as an on-site disposal technique would require dilution of the etchant with a large volume of water and a fume scrubbing system to remove hydrogen sulfide gas.

Licensed waste handlers with disposal facilities will accept spent aluminum etchant. The waste disposal facility may neutralize and de-water the resulting sludge, or use the spent etchant to treat acidic wastes. Paying someone else for complete waste disposal is probably a more expensive option, plus shipping costs are still incurred, and the risk of transporting a hazardous solution over public highways remains. For a short term operation, such as etching a short run of parts then terminating a chemical milling operation, sending spent etchant to a waste handler is the more convenient option.

Etchant Regeneration or Point Source Recovery

Spent aluminum etchants may be regenerated, i.e. spent etchant rich in sodium aluminate may be converted to sodium hydroxide (for reuse) and high quality aluminum trihydroxide that can be sold as a feedstock for other processes.

Advantages of etchant regeneration include:^[16]

- Resource recovery.
- Waste minimization.
- Pollution control.
- Consistent Dissolved Metal Content (N_2).
- Chemical use reduction (NaOH recovered and reused).

Etchant regeneration is attractive for chemical milling operations that use large volumes of etchant, or where local restrictions on hazardous waste disposal/transport make hazardous waste reductions imperative. One important advantage of etchant regeneration is that consistent etchant chemistry is maintained, thus promoting consistent product quality. Etchants that are operated from low to high N_2 and then dumped when N_2 exceeds a value of 14–17 produce large variations in chem-mill undercut.

Before selecting a regeneration process it is imperative that all systems and techniques are reviewed. Where possible, on-site reviews of operating systems should be pursued. Manufacturers of regeneration system should be able provide a list of customers and assist with visitation arrangements. Virtually all etchant regeneration technologies are Patent protected in some form – they may use a unique membrane material or use the optimum water dilution ratio, etc.

Etchant Regeneration by Dilution Diluting spent aluminum etchant with water will precipitate aluminum trihydroxide and regenerate sodium hydroxide for reuse in the etchant.^[17]

Variants of the dilution regeneration process employ a filter press or centrifuge to remove smut; special settling tanks and “seeding” compounds (floculants) to facilitate solutions removal or $\text{Al}(\text{OH})_3$ quality. Dilution based regeneration processes (Fig. 38) work best with Type I aluminum etchant, however there are two proprietary dilution systems that are operating with Type II etchants and producing acceptable results.

Membrane Based (Diffusion Dialysis) Etchant Regeneration When two solutions of different concentrations

Traditional Recovery Process Scheme

Fig. 38 Etchant regeneration—dilution process

are separated by the right kind of membrane, their concentrations change in the direction of becoming equal. Once the solution concentration everywhere within the diffusion chamber is same, the process stops.^[18] The Diffusion Dialysis process employs a unique membrane material to separate sodium hydroxide from spent etchant. Purified etchant consisting of sodium hydroxide, dissolved aluminum and the etchant additives is transferred to a crystallization process where aluminum trihydroxide and aluminum metal is extracted. The remainder, or “regenerant,” consisting of sodium hydroxide, etchant additives and a small amount of dissolved aluminum is transported back to the aluminum etchant (Fig. 39).^[17]

The engineering details of etchant regeneration by diffusion dialysis have been worked out by Malek, Incorporated. Malek’s performance claims regarding the diffusion dialysis process is that pretreatment of spent etchant by membrane simplifies aluminum trihydroxide precipitation and increases yield, i.e. with membrane pretreatment 50% of available aluminum is recovered, verses 10% by

Fig. 39 Etchant regeneration—diffusion dialysis

Fig. 40 Etchant regeneration—electrodialysis

the dilution process. In addition, a large portion of etchant additives such as triethanolamine and sodium sulfide are captured in the regenerant and returned to the etchant, hence use of additive chemical necessary for chemical milling are decreases also.

Electrodialysis Etchant Regeneration Electrodialysis is an electrochemical process that also employs a cation permeable membrane. As with diffusion dialysis, electro-dialysis involves transport of ions through an ion permeable membrane, however electrodialysis includes a motive force to speed ion transport through the membrane. The electromotive force is the electrical potential between an anode and cathode (Fig. 40).^[19]

As with diffusion dialysis the etchant is pretreated to remove sodium hydroxide. The purified etchant is then treated to remove aluminum hydroxide and the regenerant consisting of remaining sodium hydroxide, a small amount of dissolved aluminum and etchant additives is returned to the process.

Aluminum etchant regeneration by the electrodialysis process was jointly developed by Martin-Marietta and Ionsep Corporation and employs an Ionsep™ electrochemical cell with proprietary Ionsep™ anolyte additives (Fig. 41). Spent etchant is introduced into the anolyte compartment where aluminate hydrolyzes to form insoluble aluminum hydroxide. Formation of aluminum hydroxide is enhanced by electrolysis and by pH control. The free sodium cation crosses the membrane to the catholyte where it combines with hydroxide to form sodium hydroxide. Other metals such as copper and zinc remain as insoluble metal hydroxides in the anolyte compartment. Most of the etchant additives remain in the anolyte and

Fig. 41 Ionsep electrochemical cell

are reclaimed in the regenerant that is eventually returned to the process. As with diffusion dialysis, small additions of additives to the process will be necessary as some of the additives are lost with the solids removed by the regeneration process. Concentration of sodium hydroxide in the catholyte is controlled by etchant feedrate into the anolyte, and the potential across the electrodes.^[19]

The yields of sodium hydroxide and aluminum trihydroxide are highest with electrodialysis, however pH control in the anolyte solution is critical to prevent formation of hydrogen sulfide. In practice a fume scrubber would likely be necessary at the electrolyzer station (Ref. Fig. 40).

Etchant Regeneration Summary The dilution process requires more floor space and yields less, but uses inexpensive components, in relative terms. Diffusion dialysis is a passive form of etchant regeneration relative to

Electrodialysis. Electrodialysis is faster and yields more, but requires greater energy input. Diffusion dialysis and Electrodialysis systems are modular and comprised primarily of plastic components, hence maintenance is simplified.

A complete analysis of all regeneration processes by the end user is necessary to insure that all issues of factory floor space requirements, energy use, capacity and process yields are carefully evaluated.

Aluminum Etchant as Feedstock

An attractive alternative to etchant regeneration is use of spent aluminum chem-mill etchant as a feedstock for other processes. For example, if an aluminum chemical milling operation is within reasonable distance of an aluminum reduction operation, spent aluminum etchant can be used as feedstock for purification of bauxite. Bauxite is purified with sodium hydroxide before electrolysis and reduction of aluminum. Spent aluminum etchant is rich in sodium hydroxide and can therefore be used in the bauxite purification process. Aluminum etchant additives do not influence the bauxite purification process, but companies receiving spent etchant will require analysis of spent etchant to insure that no undesirable elements reach their process.

Disposing of spent aluminum etchant as a feedstock eliminates a hazardous waste, but shipping costs are still incurred, and the risk of transporting a hazardous solution over public highways remains.

Quality Issues

Chem-mill quality issues by Cause and Effect Diagrams (Fig. 42):

The majority of quality issues in chemical milling center on the etchant and its influence on process attributes. Undercut ratio and set-back factors used by tool-makers are influenced by etchant constituents, dissolved metal in solution, etch temperature and part loading techniques employed by operators. Static tools coupled with a dynamic process will cause significant quality problems. In aerospace this situation translates into expensive rework in assembly, and parts that may be within dimensional tolerance, but heavier than the expected nominal weight. Both situations cost the customer in terms of higher product costs, and higher fuel expenditures.

Aerospace Example

A chemical milling department received a commercial air transport part for processing (Fig. 43).

The chem-mill tool was constructed by the original equipment manufacturer and was used directly, however, the undercut ratio used to determine the tool offset was sufficiently different from the average process undercut ratio that all chem-mill land areas were undersized. Thus, the entire order of parts was rejected and scrapped. Approximate value of the parts at the time the order was scrapped: \$11,000 Taguchi Loss Function for the Chem-Mill Example.

Design of Experiment/Taguchi techniques are important tools for improving process quality.^[20]

Fig. 42 Quality issues in chemical milling

Fig. 43 Critical dimension produced by chemical milling

Application of Quality Tools in Chemical Milling

All parts are inspected following the chemical milling process as required by contract. Quality measures are: (1) depth of chem-mill cut; (2) absence of burn marks or pits caused by etchant leaking through thin spots in the maskant coating; (3) surface finish in the chem-mill cut area; (4) location and dimensions of chem-mill lines and land areas (Figs. 25–28). Allowable tolerances are established for each parameter by the engineering drawing. If all measures fall within the allowed tolerance the parts are considered to be acceptable for use and are forwarded to the next process for painting and eventual assembly.

Problems/Quality Deficiencies

Often, when new scribe tools are released for use in manufacturing, the parts produced do not meet allowable tolerances. To correct the problem a tool maker modifies the scribe tool, effectively changing the undercut ratio, or etch factor. Two to four iterations of tool modifications are typically necessary. Holding parts in queue while scribe tool modifications are completed and tested causes production schedule delays.

Parts that are within allowable tolerance still cause assembly interference (Fig. 44).

To correct the interference problem assembly workers must manually grind excess material from the

Fig. 44 Part to part interference in chem-mill fillet

chem-mill pocket. After grinding is complete, the corrosion preventive coatings, (conversion coating and paint), must be repaired and the parts reassembled. Part rework that occurs during the aircraft assembly phase is most expensive, and has the greatest impact on production and delivery schedules. The study efforts for undercut ratio may be organized by the following seven guidelines:^[21]

- Recognition and statement of problem.
- Choice of control factors and levels.
- Selection of the response variable.
- Choice of experimental design.
- Experiment execution.
- Data analysis.
- Conclusions and recommendations.

Recognition and Statement of Problem

Chem-mill tank operators will explain that the actual undercut ratio changes as metal is dissolved by the etchant. For some alloys, many iterations of tool modifications are performed to find an undercut ratio that will produce acceptable parts throughout the process. The situation forces operating personnel to:

- Obtain material and test new chem-mill tools. The point estimate of undercut ratio generated by the test was not applicable throughout the process.
- Scrap and replace parts when the target value for undercut ratio is not achieved and a chem-mill land width or line location is out of tolerance.

The following 8 control factors are judged to have an important influence on the chem-mill undercut ratio:

- metal alloy
- heat treat, or age condition
- clad coating or bare metal
- etchant temperature
- triethanolamine concentration
- amount of dissolved metal in solution, N_2
- amount of free sodium hydroxide in solution N_1
- depth of chem-mill cut
- part load position

Note that the amount of dissolved metal in solution, N_2 , and the amount of free sodium hydroxide in solution, N_1 , are continuous variables.

Control Factor Level Selection

Levels for the respective control factors are defined on engineering drawings and in process specifications. However, the operators may often run the process inside, or outside of specified levels to improve process efficiency. Therefore,

Table 12 Process control parameters, process versus specification

	Actual levels		Process spec.	
	(−)	(+)	(−)	(+)
Control Factors	(−)	(+)	(−)	(+)
Depth of Cut	40	140	15	200
Etch Temperature	195–205	210–220	190	220
Free Caustic	24	34	21	34
Dissolved Metal	2	14	0	14
Load Position	45	90	none	none

operating levels indicated by the process operators should be used (Table 12).

Quality Tools Application

Once execution of the experiment is complete, data can be used to develop regression models that describe undercut ratio, or any other measured response, in terms of the process (Table 13)

$$\begin{aligned} \text{Predicted Undercut Ratio} = & 8.3429 - 0.04342(\text{DOC}) \\ & - 0.02062(\text{TEMP}) - 0.0186(N_1) - 0.0589(N_2) \\ & + 0.002948(\text{POS}) + 0.00008816(\text{DOC})^2 \\ & + 0.000101(\text{DOC} \times \text{TEMP}) \end{aligned} \quad (20)$$

The process regression model is most important as the model can be used by chem-mill operators to predict undercut ratio results and control the chem-mill process to achieve a desired outcome.

Before relying on the regression quality tools such as Residual Plots and regression model confirmation via Hypothesis Testing or other quality tool is recommended.

In “Waste Disposal” section, etchant regeneration is described as a way of controlling etchant chemistry such that consistent surface finish, fillet quality and undercut ratio are always produced. Certainly, etchant regeneration holds such an advantage, however Design of Experiment techniques coupled with development of process regression models allows operators to predict undercut ratio and schedule jobs accordingly. Hence, aluminum etchant can be operated without etchant regeneration and still produce consistent part quality.

Taguchi Loss Function, Nominal-is-Best—general case for Chemical Milling.^[10,22] Taguchi’s Loss function can be used to estimate cost reductions realized by using quality tools for better process control (Fig. 45).

$$\text{Loss to Society, or Enterprise} = k[S^2 + (y - m)^2] \quad (21)$$

where: k = coefficient

S = Standard Deviation

y = Target Value

m = Actual, or Measured Value.

**Fig. 45** Taguchi loss function—costs incurred for failure

Some loss is incurred whenever a target undercut ratio is not achieved. Equation 21 defines undercut ratio as the quotient of undercut and chem-mill depth of cut. Hence when a target undercut ratio is not achieved, labor hours must be expended to correct the chem-mill undercut. Therefore, for the Loss Function example, the cost to repair chem-mill undercut is estimated. Undercut is calculated by rearranging Eq. 13, (Ref. Fig. 23).

$$UC = UCR \times DOC \quad (22)$$

Assembly interference can result when the target undercut ratio value is not achieved (Ref. Fig. 44). Parts such as the one depicted are not generally scrapped because the

chem-mill line location is within the allowed ± 0.03 in. tolerance. Instead, the parts are reworked to eliminate the interference.

For the general case of the Taguchi Loss Function, only the rework cost be considered, i.e. the loss function estimates the cost of rework per part if the problem is corrected in the chemical milling department. In reality, if the part is reworked during assembly operations there would be additional costs to cover rework of conversion coatings and paint repair.

The Taguchi Loss Function for the Chemical Milling example:

- From Eq. 21, the coefficient k :

$$k = (\text{Loss})/\text{tolerance}^2 \quad (23)$$

- Assume the cost to move a chem-mill line is approximately \$0.17/linear in. (Ref. Fig. 45).
- An undercut that causes parts to be rejected would be the result of an undercut ratio that produces a chem-mill line mislocation of ± 0.03 in. Substituting into Eq. 20, the loss (L) incurred if the chem-mill undercut must be reworked: Calculate k :

$$k = [(\$0.17/\text{in.})/(\text{0.03in.})^2] = \$189/\text{in.}^3$$

- The Mean Square Error estimate of Variance (S_{UCR}^2) of undercut ratio from the quadratic model for undercut

ratio^[20] (Ref. Table 12). S_{UCR}^2 includes the effects of systematic and instrument error observed in the gage repeatability and reproducibility study. Note that undercut ratio is without units, therefore, S_{UCR} and $(y - m)$ are also without units. Substituting into Eq. 21, the loss/part is:

$$\begin{aligned} \text{Loss/part} &= k[S_{UCR}^2 + (y - m)^2] \\ \text{from Eq. 23, } k &= \$189/\text{in}^3, \text{ therefore} \\ &= \$189/\text{in}^3 [S_{UCR}^2 + (y - m)^2] \\ &\quad - \$/\text{in}^3 \end{aligned}$$

- The Loss/part is expressed as a volume (in^3). As defined in Eq. 23, undercut is directly proportional to undercut ratio. Chem-mill undercut defines the location of the chem-mill line, if the line is mislocated the chemical milling operator or its customer must incur the cost to manually grind away a volume of metal to correct the chem-mill line location and pocket radius (Ref. Fig. 4).

The total cost, or loss/part is directly proportional to the volume of metal that must be removed, which, is the multiple of the target undercut less the actual undercut (AUC); the depth of cut, and the length of chem-mill line, or the perimeter of all chem-mill pockets on the part. An expression for the volume of metal that must be removed due to incorrect undercut ratio is:

$$VM = (AUC)(DOC)(\text{Pocket Perimeter}) = \text{in}^3 \quad (24)$$

For the aircraft part (Ref. Fig. 44) $\Delta UC = 0.03 \text{ in.}$; $DOC = 0.05 \text{ in.}$, and the part has 731 linear in. of chem-mill lines. Then, substituting into Eq. 24:

$$VM = (0.03 \text{ in.})(0.05 \text{ in.})(731 \text{ in.}) = 1.1 \text{ in}^3$$

- Modifying the Taguchi Loss Function, Eq. 21, by multiplying by Eq. 24 produces a new expression for the loss/part:

$$\text{Loss/part} = (VM)k[S_{UCR}^2 + (y - m)^2] \quad (25)$$

- For the aircraft part (Ref. Fig. 44) the actual undercut ratio achieved (y) was 1.8, the target value (m) was 1.2. $S_{UCR}^2 = 0.01324$ (Ref. Table 12). The coefficient k from Eq. 25, $k = \$189/\text{in}^3$, and from Eq. 23, $VM = 1.1 \text{ in}^3$. Substituting all values into Eq. 25 produces an estimate of the loss/part due to incorrect undercut ratio.

$$\begin{aligned} \text{Loss/part} &= (1.1 \text{ in}^3)(\$189/\text{in}^3)[(0.01324) + (1.8 - 1.2)^2] \\ &= \$77.60/\text{part} \end{aligned}$$

- If the target value for undercut ratio is achieved within 1.5 sigma (Motorola uses this factor as a rule of thumb to account for typical shifts and drifts of process averages),^[12] then the loss per part due to process shifts is:

$$\begin{aligned} \text{Loss/part} &= (VM)k[(2.385)(S_{UCR})^2] \\ \text{Loss/part} &= (1.1 \text{ in}^3)(\$189/\text{in}^3)[(2.385)(0.01324)] \\ &= \$6.56/\text{part} \end{aligned}$$

$$\text{Net savings} = \$77.60 - \$6.56 = \$71.04/\text{part}.$$

Use of quality tools in chemical milling can generate substantial savings. Process Data could be presented to operators by Response Surface Charts (Fig. 46), or perhaps process procedure cards. Process Procedure Cards could be created by part number and a program written to use operator input to determine and display ideal operating

Fig. 46 Response surface chart—chem-mill undercut ratio

Fig. 47 Reference card system schematic

conditions for parts with critical pocket, line, or land dimensions (Fig. 47).

MATERIAL SELECTION FOR TANKS AND PART RACKING

Type II aluminum etchants are popular due to surface finish and etch rate improvements. The typical scenario for introduction of Type II etchant in the aerospace industry was to drain the Type I etchant, and then prepare and use the Type II etchant in existing process tanks. Some time later, failure of the process tank occurred. Large cracks appeared at the weld seams. The tanks could not be repaired and severe schedule delays were incurred.

The materials selected must resist the corrosive effects of specific solution used for aluminum chemical milling. Chemical milling operation typically employ Type I or Type II Aluminum Etchants, a Desmutter or Deoxidizer and rinse water. The materials selected for tanks and work racks are acceptable for both etchant types, but requirements for Type II aluminum etchants will be studied in detail.

Type II aluminum etchants consist of sodium hydroxide triethanolamine, sodium polysulfide and the remainder is water, (chlorine content varies by location). Operating temperatures are 190° F to 225° F. Normal etch rate on aluminum is 0.001–0.003 in/min. Occasional splashing that occurs during solution preparation may expose the tank material to 50% sodium hydroxide at ambient temperature.

Desmut or deoxidize solutions may consist of nitric acid and sodium dichromate, or a mix of nitric and hydrofluoric acid. Small amounts of sodium dichromate or hydrofluoric acid may produce brighter parts, due to environmental and safety concerns, both compounds are generally avoided where possible. A typical desmutting solution for aluminum chemical milling is equal volumes of water and 42° Be' Nitric Acid. Desmutting solutions are used at ambient temperature.

Process tanks are welded structures specified with water-tight welds. Process tanks are normally constructed at small fabrication shops that possess limited fabrication and welding capability. Therefore, the materials selected must be compatible with conventional welding techniques, i.e. electric arc “stick” welding, or inert gas arc welding. The process tank must support and contain chemical processing solutions. Loads will be uniform, increasing from tank rim to tank bottom. Impact loading may occur should an operator drop a process basket. The material selected must resist abrasion as operators frequently scrape the tank walls with process baskets.

Candidate materials for tanks and work racks frequently exposed to the aluminum etchant are those low in carbon, manganese, and sulfur, but higher in chromium, copper, nickel and molybdenum. Sodium hydroxide is considered as the primary corrosive constituent. As noted, Type II etchant also contain triethanolamine and sodium sodium polysulfide (some etchant formulas substitute sodium sulfide for sodium polysulfide). In low concentrations neither the amine or the sulfide appear as important as sodium

hydroxide in the corrosion mechanism.^[23] It is possible that at least two and perhaps all etchant constituents interact to produce higher corrosion rates. For example, corrosion resistance tables suggest a uniform corrosion rate of stainless steel in a 15% hot caustic solution of less than 0.02 in. per year.^[24] Actual uniform corrosion rates measured in an aluminum etch tank are greater than 0.04 in./yr, but did not exceed 0.05 in./yr. Determining the relative affects of the etchant constituents on tank and work rack materials could be accomplished by design of experiment techniques. Such efforts are better expended on improving quality of aluminum chemical milling. Instead, a formula for determination of tank lining degradation can be derived and maintenance or tank replacement schedules can be developed around tank degradation predictions.

Etch Tank Service Life Estimation

Calculation example: 316 stainless steel plate, removed from tank lining material is tested in Type II aluminum etchant. The etchant is 20–30% sodium hydroxide and is operated at 215°F. The apparent density of the sample is 0.287 lb/in³. Test specimen dimensions (Fig. 48) are $l = 5.906$ in.; $w = 1.505$ in.; $t = 0.251$ in. Initial sample mass is 284.2297 g, and final sample mass (after etching) = 269.6042 g.

$$dM = 284.2297 - 269.6042 = 14.6255 \text{ g.}$$

$$ds = dM / [2\rho(yz + xz + xy)]$$

$$ds = 14.6255 / [2(0.2872)(1.505)(0.251) + (5.906)(0.251) + (5.906)(1.505)]$$

$$ds = 0.005203 \text{ in.} [(Kg/1000g)(2.204)lb/Kg)/lb/in.]$$

$$\Delta t = 31 \text{ days} / 278 \text{ manufacturing days (days in use)} = 0.112 \text{ yrs.}$$

$$\therefore \text{etch rate} = 0.047 \text{ in./yr.}$$

$$\text{Error estimation: } \delta ds/ds = \delta dM/dM + \delta A/A$$

$$\delta dM/dM = (0.005 \text{ g}/14.6255 \text{ g}) = 0.000319$$

$$\delta A_1/A_1 = (0.05 \text{ in.}/1.505 \text{ in.}) + (0.002 \text{ in.}/0.251 \text{ in.}) = 0.0411$$

$$\delta A_2/A_2 = (0.05/5.906) + (0.002/0.251) = 0.0164$$

$$\delta A_3/A_3 = (0.05/5.906) + (0.05/1.505) = 0.0416$$

$$\therefore \delta A/A = 0.0991$$

$$\delta ds/ds = 0.000319 + 0.0991 = 0.09942$$

$$\delta ds = (0.09942)ds = (0.09942)(0.005203 \text{ in.}) = 0.0005173 \text{ in.}$$

$$\therefore \delta \text{etch rate} = (0.0005173 \text{ in.})/0.112 \text{ yr.} \cong 0.005 \text{ in./yr.}$$

The estimated etch rate of tank lining material is 0.047 in. $\pm$ 0.005 in. If 3/8 in. 316 stainless steel plate stock is used for tank construction then operators should plan for relining or lining repair in 6th or 7th year of operation. Annual measurement of tank lining thickness by ultrasonic techniques is recommended, particularly near heat exchange devices.

Fig. 48 Tank lining test specimen—plate stock

Fig. 49 Tank lining test specimen—tubing

Tubing may also be used as sample material (Fig. 49). Equations for tubing are as follows:

$$ds = dM / [\rho 2\pi h(R+r) + 2\pi(R^2 + r^2)] \quad (28)$$

Error is again, from Eq. 23:

$$\delta ds/ds = \delta dM/dM + \delta A/A$$

$$\delta dM/dM = \delta M_1 + \delta M_2$$

$$\delta A/A = [\delta h/h + ((\delta R + \delta r)/(R+r))] + (2\delta R/R + 2\delta r/r) \quad (29)$$

Although tubing may be used as sample material, experience in the aerospace industry indicates that the apparent etch rate is approximately 72% greater. It could be that tubing samples were of welded tubing, hence the heat effected zone caused an etch rate greater than that observed on plate stock. Hence, tubing is not a good test specimen material for the tank lining, but is a good choice if tubing is used for any in-tank piping. The best specimen for tank linings

is material cut directly from the material used for tank construction, lining or repair.

The affects of the etchant constituents are considered separately. For Type II aluminum etchants the candidate materials for tank and work rack fabrication are plain carbon steels, high strength low alloy steels, and chrome/nickel based alloys.

Materials for Etch Tank Construction

Plain Carbon Steels

Corrosion resistance is sufficient in low temperatures, as demonstrated by years of reliable service with Type I etchants. As temperature and sodium hydroxide concentrations increase mild steel structures are subject to stress corrosion cracking (SCC) in the weld joint heat effected zone (HAZ).^[25] This phenomenon has been observed in mild steel process tanks used in the aerospace industry. Post weld stress relief of the tank may alleviate SCC in weld joints, but stress relief of most large tank structures is impractical. Vibratory stress relief techniques may be useful for large tanks.

Stress relief coupled with a reduction in etchant operating temperature to less than 200°F could make carbon steel an acceptable choice, however reducing etchant temperature will also reduce etch rate and process output. Therefore, mild steels are not a good choice for this process application.

Low Alloy, or Weathering Steels

Weathering steels provide improved atmospheric corrosion resistance, but show no significant improvement in corrosion resistance in immersion service.^[25]

Ferritic Stainless Steels

Ferritic stainless steels should not be considered due to carbon content. Chromium carbides that precipitate in weld HAZ can result in SCC when the material is exposed to hot sodium hydroxide solutions.^[26]

Austenitic Stainless Steels

Types 304 and 316 are acceptable for use in hot sodium hydroxide solutions to temperatures of 250°F. SCC remains a concern with austenitic stainless steels. Type 304 tanks used in the aerospace industry exhibited evidence of SCC in the weld HAZ, and intergranular corrosion in the weld fill area. Rapid corrosion occurs in the HAZ adjacent to the weld deposit due to chromium carbide precipitates. Corrosion of Type 304 can be minimized by using 304L (low carbon, 0.03–0.08%), and use of preferential carbide formers such as Tantalum or Columbium. Tantalum or Columbium will prevent formation of chromium carbides

at the grain boundaries, thus the chrome content in the HAZ is not depleted and intergranular corrosion is prevented.

High Nickel Alloys and Super Alloys

Nickel 200 and 201, Hastelloy® grades and Inconels are excellent choices. The nickel based alloys provide unsurpassed resistance to corrosion by hot sodium hydroxide solutions.^[27] Unfortunately, when the cost of Inconel 625 is compared to Type 304L Stainless Steel the high nickel steels are approximately 5–6 times more expensive than austenitic stainless steels. Use of the high nickel alloys is considered cost prohibitive.

Use of Type 304L Stainless Steel is considered the best material choice for tank construction. Use of Columbium stabilized welding rods, or wire, (e.g. Type 308 or 347 stainless steel)^[28] will minimize the possibility of SCC and intergranular corrosion. Plain carbon steel, AISI grades 1005–1008 can be used for exterior tank structure. To prevent galvanic corrosion or crevice crack corrosion all carbon steel must be covered with a stainless steel drip shields. The shields should be attached by continuous weldment, or tack welded and caulked as appropriate for a water-tight barrier.

An often selected alternative is to construct the tank of low carbon steel and then insert a 304L stainless steel “drop-in” liner. A liner is undesirable because

- Should water leak between the liner and tank shell a galvanic cell will exist. Stainless steels are cathodic and mild steel is anodic when coupled by a corrosion media,^[29] thus the tank shell will eventually sustain corrosion damage.
- Fabricating liners within a tank is difficult, particularly around tank outlets. Material distortion of thin gage liners is a problem, which will likely result in liner failure, and the beginning of a corrosion problem.

Materials for Desmutting Tank

Austenitic Stainless Steels

Austenitic Stainless Steels provide excellent corrosion protection from nitric acid solutions. Austenitic grades such as 304 are not recommended for hydrofluoric acid service when hydrofluoric acid concentration is less than 70%. Therefore, direct and continuous contact of austenitic stainless steels with the desmut solution is not recommended.

Hastelloy™

Hastelloy™ C-276 provides acceptable corrosion resistance to both nitric and hydrofluoric acids, and it can be fabricated by common welding techniques. Hastelloy™ resists

formation of grain boundary precipitates in the weld HAZ, however the high cost of high nickel alloys is prohibitive for large tank structures.

Tank Lining Materials

Tank lining materials are used in many chemical processing applications. Liner types range from “bag” to drop-in liners. Bag liners are identical in form to the rubber liners used in swimming pools, and drop-in liners are fabricated from rigid plastic sheet materials and dropped into the tank shell. Bag liners are a poor choice as they are easily punctured and abraded. Drop-in liners provide more reliable service if the liner fits correctly. For all tank liner types, failure means extended process line down-time while tank contents are removed and linings and tank shells are repaired.

Polyvinyl Chlorides

Rigid PVC sheets or Koroseal™ are acceptable materials. Both materials may be used to fabricate drop-in liners. Operating experience in the aerospace industry has demonstrated that both materials, rigid PVC in particular, fail frequently (approximately once per year) resulting in tank shell damage. Koroseal is flexible and can be bonded to a metal tank shell.^[30] Bonded liners conform to surface undulations. Koroseal liners have excellent abrasion resistance, which will limit damage caused by a wayward process basket. When damage to the tank shell does occur, the bonded lining will flex with the steel tank shell and retain the process solution. Tank shell damage incurred due to pinholes leaks, lining abrasions, etc. will be localized as process solutions cannot easily propagate behind a bonded liner as it could if the liner type were a drop-in or bag liner.

Elastomers

Elastomeric lining material can also be bonded directly to the steel tank shell. Elastomers must be vulcanized after bonding; steam is used to vulcanize the elastomer. Butyl Rubber is a candidate elastomeric material for Nitric/HF desmutting solutions used at ambient temperatures.

Polyvinyl Chloride (Kynar): Polyvinylidene Fluoride (Kynar™)

Kynar™, or PVDF provides excellent chemical resistance to both nitric and hydrofluoric acids. Kynar is the best choice for temperatures up to 284°F, however Kynar is 6 times more expensive than Koroseal. For desmutting, which is performed at ambient temperature, Kynar is cost prohibitive.

Fiberglass Reinforced Plastic (FRP)

FRP structures are excellent alternatives to rubber lined steel tanks^[31] for special applications such as high etch temperatures or high concentrations of nitric/hydrofluoric acid. For tank volumes about 3000 gal FRP structures become difficult to fabricate. The relative costs of FRP tanks are twice that of mild steel and 1.3 times that of stainless steel.

Conclusions: Best choice is a 304L stainless steel tank shell with carbon steel exterior support structure. Do not use hydrofluoric acid as a constituent in the desmutting solution. Hydrofluoric acid in an aluminum desmutting solution will make part “brighter”. But aside from value, use of hydrofluoric acid will add nothing to the overall process.

Fume Scrubbers

Fume scrubbers for aluminum chemical milling with acid desmutting can be conventional packed or cross-flow water wash scrubbers with pH control. Stainless steel, PVC or polypropylene are ideal materials for fume scrubber construction. Slot ventilation at the tank rim is adequate for fume control, provided tank width does not exceed 4–5 ft. For wider tanks the user must consider additional adjacent ventilation, passive surface cover such as floating plastic balls, or active tank covers. For large etch tanks (10 ft wide or greater) slot ventilation at the tank rim in conjunction with active tank covers a vented hood that surrounds the crane. The combination of ventilation techniques allows for minimal ventilation while the tank cover is closed and maximum ventilation when the tank is in use.

Maskant Tank Materials

Solvent-Based Maskants

Carbon steel is sufficient for tank construction.

Waterborne Maskants

Stainless steel, 304L, is an excellent material for mask tank construction. Plain carbon steels cannot be used for direct continuous contact with waterborne maskants due to oxidation problems.

Plain carbon steel lined with polypropylene (bonded to the steel tank wall) is an acceptable alternative to stainless steel. Plain carbon steel structure supporting a polypropylene tank is also acceptable for large tanks. If the required tank volume is only 1000 gal or less, then a tank constructed completely of polypropylene should be considered. Tank suppliers can provide assistance with proper material selection.

Fig. 50 Typical etch line automation planning

Fig. 51 Flexible etch line automation

PROCESS ORGANIZATION

Chemical milling includes 5 distinct steps that naturally migrate to clean, mask, scribe, etch and demask, which are generally located in one facility. Process flow may be straight line, or be arranged in a “U” shape depending upon the building configuration, number of shipping docks, etc.

Queuing for the process should be arranged such that one part queue is maintained in the scribing area. In reality, there will also be a queue area in masking and etching. The masking and etching queues should be considered as secondary and minimized to the greatest extent possible. Assuming the masking operation is an automated immersion or spray system, the scribing operation will be the most labor intensive. Second most labor intensive is part basket loading and etching.

Automation of the etching operation has been attempted at many facilities with varying degrees of success. Automated etch lines tend to maximize output of simple chem-mill part configurations while complicating the process for parts that include chemically milled tapers. A typical etch line automation plan arranges etch, rinse, desmut and final rinse in order. Producing a chemically milled taper requires a hoist remain stationary over the etch tank as it is used to raise and lower the part. Automation plans (Fig. 50) would stop all etch line work while a taper is produced*.

*Alternative schemes such as using high volume pumps and a holding tank to pump etchant to and from the tank, or using a lift to raise and lower the tank are feasible, but many times more complicated and costly.

The etch line configuration (Fig. 51) allows for automation and for special work to be processed at one end of the etch line while general work is completed at the other end.

PROCESS POTENTIAL

The primary use of chemical milling in the aerospace industry is for removing unneeded material from sheet metal parts. The same condition exists with machined parts. The thickness of machined webs is limited by cutter deflection and machine tool vibration, hence webs must remain heavier than is actually necessary. The aerospace industry has invested enormous amounts of money in new high speed machining technologies that allow fast machine feedrates without machine tool vibration, and allow production of thinner machined webs. Development of high speed machining has continued while the industry has essentially ignored the achievements of British Aerospace^[1] while fabricating machined parts for the Concorde supersonic passenger jet. Machine tools of the time were not capable of producing the thin web sections necessary, so the parts were machined as far as practical, then immersed in chemical milling etchant for an overall stock reduction. Parts produced by this process exhibit improved surface finish after etching, and they are ready for non-destructive testing (penetrant inspection) without further processing.

Large removals by etching will generally produce an etch rate differential between thin and thick web sections, but this problem can be addressed by designing

for chemical stock reduction and sizing the web sections accordingly.

The chemical milling process may eventually find use in the automotive industry as automobile designers use lighter materials such as aluminum and weight savings techniques to reduce automobile weight and fuel consumption. Chemical milling, once and perhaps still, popular with race teams, was a technique for stock reducing metal car bodies to provide a weight advantage over other race cars.^[1]

As used in aerospace, chemical milling does not fit the requirements of mass production. Cycle times for liquid maskant application and manual scribing are prohibitive in mass production settings. Developing maskant products that apply in a fashion similar to that of adhesive tapes, with pre-cut pockets or other features would speed maskant application and eliminate scribing. Parts could remain on original conveyance through masking, etching and demasking. A “mass production” chemical milling process would be analogous to automotive painting operations. For now, chemical milling is used primarily for aerospace applications.

APPENDIX A

Derivation of Equations (1) and (2)

1. The relation used to generate Appendix A, Fig. 52 is derived from Table 14:

$f(n) = 5800n/6000$. The relation is used as follows:

$$f(6000) = 5800(6000)/6000 = 5800,$$

$$f(5800) = 5800(5800)/6000 = 5606.7,$$

$$f(5606.7) = 5800(5606.7)/6000 = 5419.8, \text{ etc.}$$

The relation cannot be defined as a numerical sequence as (n) is not an integer value in most cases.

Fig. 52 Mask age versus time (hrs) reconstruction of maskant versus time relationship. (Courtesy of R. G. Werkema.)

However, suppose $f(n)$ were a numerical sequence. The graph of Appendix I, Fig. 1 depicts a function that approaches infinity while converging on zero (0). Taking the limit of $f(n)$ as (n) goes to infinity:

$$\lim_{n \rightarrow \infty} f(n) = \lim_{n \rightarrow \infty} 5800n/6000 \neq 0$$

Thus, the original relation, when defined as a sequence describes a function that is divergent, i.e. the function does not converge on any real number value. Therefore, the relation is not a correct description of Appendix A, Fig. 52.

2. The relation $f(n)$ can be rearranged to fit the definition of a numerical sequence.

2.1 $f(n)$:

$$f(6000) = 5800(6000)/6000 = 5800,$$

$$f(5800) = 5800(5800)/6000 = 5606.7,$$

$$f(5606.7) = 5800(5606.7)/6000 = 5419.8, \text{ etc.}$$

2.2 $f(n)$ redefined as $f(t)$:

$$\text{let } f(t) = [6000(5800/6000)]^t$$

where (t) equals time (days) and all positive integers greater than zero (0), i.e. $(t = 0, 1, 2, 3, 4, 5, \dots n)$.

$$f(t)/\text{for } 6000/t = 0, 5800/t = 1, 5606.7/t = 2, 5419.6/t = 3, \dots$$

A limit test demonstrates that $f(t)$ is convergent, and converges on zero (0).

$$\lim_{t \rightarrow \infty} 6000(5800/6000)^t = 0$$

$$t \rightarrow \infty$$

Therefore, the function $f(t)$ converges to zero as (t) approaches infinity. Thus, the function $f(t)$ adequately describes the graph of Appendix A, Fig. 52.

3. A plot of function $f(t)$ is (Fig. 53):
Careful substitution for $f(t)$ reveals a common form of a frequently used differential equation.

3.1 Let $f(t) = G_r$, gallons remaining

$$\begin{aligned} \text{Constant, } C &= 6000 \text{ gallon constant tank volume} \\ a &= 5800/6000, \text{ ratio of maskant usage} \\ G_r &= 6000(29/30)^t = C(a)^t \end{aligned}$$

Fig. 53 Mask volume versus time (days)

by definition of the natural exponential function

$$Ce^x = G_r = C(a)^t$$

$$\text{let } x = \ln G_r = \ln(a)^t$$

then $e^x = (a)^t$ (constants eliminated)
because by definition

$$\ln e^x = x$$

$$e^{\ln x} = x; \text{ then substituting for } x.$$

$$e^{\ln(a)^t} = (a)^t, \text{ and}$$

$$e^{t \ln(a)} = (a)^t$$

substituting the new expression for $(a)^t$ into G_r produces

$$G_r = Ce^{t \ln(a)}$$

which is

$$G_r = 6000e^{t \ln(5800/6000)}$$

where $\ln(5800/6000) = -3.39 \times 10^{-2} \text{ day}^{-1}$

$$G_r = 6000e^{-3.39 \times 10^{-2} t}$$

$$\text{let } k = -3.39 \times 10^{-2} \text{ day}^{-1}$$

$$\Rightarrow G_r = 6000e^{kt}$$

3.2 Application of the definition of the natural exponential function provides a new expression for the mask versus time relation. The new expression for G_r is continuous for all (t) greater than or equal to zero (0), and it converges to zero as (t) approaches infinity. The expression is a common form of the, "Law of Natural Decay".^[9]

3.3 A much easier approach is direct application of the Law of Natural Decay:

3.3.1 The rate at which the original maskant is removed from the tank with respect to time is proportional to the quantity of the

original maskant present in the tank at a given instant, i.e.

$$dG_r / dt = kG_r$$

where: dG_r = rate at which the original tank volume diminishes.

dt = change, or rate of change of time (days)

k = coefficient of mask usage

G_r = gallons of original mask remaining

$$dG_r / G_r = k dt$$

$$\int dG_r / G_r = \int k dt$$

$$\ln |G_r| = kt + C$$

$$G_r = e^{kt} e^C = e^{(kt+C)}$$

when $t = 0$, $G_r = 6000$, $e^{kt} = 1$

then $6000 = e^C$

therefore $G_r = 6000 e^{kt}$.

If maskant is used at a rate of 200 gal per day, then when $t = 1$, G_r must equal 5800 gal:

$$6000 - 200 = 6000e^{(1)}$$

$$5800/6000 = e^k$$

$$\ln(5800/6000) = k$$

$$-3.39 \times 10^{-2} = k$$

which is the same coefficient derived in paragraph 3.1.

3.4 As demonstrated, direct application of the Law of Natural Decay produces an expression for mask time in tank. However, the technique fails to demonstrate that logic used to generate Appendix A, Figs. 52 and 53 is in fact correct.

Continuity and Asymptote Testing of Equation 1

1. Test the expression $G_r = 6000 e^{kt}$ for continuity and asymptotes. A convergence test of the expression was completed in Appendix A, paragraph 2.2.

1.1 Continuity Test: A function is said to be continuous at the number (t) if and only if the following three conditions are satisfied.

a. $f(t)$ exists

b. $\lim_{x \rightarrow t} f(x)$ exists

c. $\lim_{x \rightarrow t} f(x) = f(t)$

Let $f(t) = G_r$, when $t = 0$, the volume of the original tank charge must equal the constant tank volume, i.e. at $t = 0$, the entire tank must be filled with new maskant.

a. $f(t) = f(0) = 6000 e^{k(0)} = 6000$, thus $f(t)$ does exist.

b. Let $f(t) = f(x)$

$$\lim_{x \rightarrow t} f(x) = \lim_{x \rightarrow t} 6000 e^{kx}; t = 0$$

$$\lim_{x \rightarrow t} 6000 e^{k(0)} = 6000, \text{ thus the limit does exist.}$$

- c. Summary, from parts 1.1(a) and 1.1(b): (1) $f(t)$ exists and equals 6000; (2) the limit of $f(x)$ as x approaches zero (0) exists and is equal to $f(t)$. Therefore, the expression for gallons remaining, G_r , is continuous for all (t) .
2. The line $y = b$ is said to be a horizontal asymptote of the graph of the function (G_r) if at least one of the following statements is true.
- Let $G_r = f(t)$
- $\lim_{x \rightarrow +\infty} f(t) = b$, and for some number N , if (t) is greater than N , then $f(t)$ does not equal (b) .
 - $\lim_{x \rightarrow +\infty} f(t) = b$, and for some number N , if (t) is greater than N , then $f(t)$ does not equal (b) .
- Therefore:
- $\lim_{x \rightarrow +\infty} f(t) = \lim_{x \rightarrow +\infty} 6000 e^{kt}$; for $k = -3.39 \times 10^{-2} \text{ day}^{-1}$ $\lim_{x \rightarrow +\infty} 6000 e^{-kt} = \lim_{x \rightarrow +\infty} 6000/e^{kt} = 0$
- As (t) becomes large, the ratio of (G_r) $6000/e^{kt}$ converges to zero (Fig. 54).
- Since the limit of $f(t)$ is zero as (t) approaches infinity $(+\infty)$, $f(t) = G_r = 0$ is a horizontal asymptote. Thus, as (t) becomes large, G_r converges on zero, but never actually equals zero.

Derivations of Equations (2), (3) and (4)

Definition, Impeller Cycles: The number of times the original tank charge of maskant, or some remnant thereof, passes through a mixing impeller.

- A production mask tank contains 6000 gal of maskant. To simplify equation derivation, assume that a single large impeller is used to mix and circulate the maskant. The unit of time considered is one 24-hour day, manipulated as necessary.
 - Assume the pumping rate of the mixing impeller is 6000 gal/min. The impeller must be stopped for each part immersion cycle to prevent loss of parts from part racks. Assume that immersion cycles occur every 9.5 min and the transfer time of part racks into the lowering device, or

hoist, is 1 min. Thus, six immersion cycles occur each hour, and the entire tank volume is mixed six times each hour, or 36,000 gallons of mask is pumped per hour.

$$(36,000)(16) [\text{gal} \cdot \text{hr} / \text{hr} \cdot \text{day}] = 5.76 \times 10^5 \text{ gal/day}$$

$$C_1 = (5.76 \times 10^5 / 6000) [\text{gal} \cdot \text{cycles/day} \cdot \text{gal}] \\ = 96 \text{ cycles/day}$$

Therefore, the entire mask tank volume will be cycled through the mixing impeller 96 times each day. Since the volume of the original mask declines relative to time, the number of impeller cycles to which the original mask is subjected will decline at the same rate.

- The number of impeller cycles may be expressed as the ratio of original mask remaining to the total volume of mask, multiplied by the number of impeller cycles occurring each day, e.g. after day one of operation, 5800 gallons of original mask remain:

$$(5800/6000)(96 \text{ cycles/day}) = 92.8 \text{ cycles/day}.$$

Thus, at the end of day one, the original mask is cycled approximately 93 times/day.

$$I_c = C_1 e^{kt} = 96 e^{kt} [\text{cycles/day}] \quad (2)$$

where I_c = Impeller Cycles, rate for original tank charge at any time (t), cycles/day.

C_1 = Average number of impeller cycles occurring each day, for the entire tank volume, cycles/day. Impeller Cycles per unit time

t = time, days

k = coefficient of mask usage, day^{-1} .

for $I_c = 92.8 \text{ cycles/day}$

$$k = \ln(92.8/96) = -3.39 \times 10^{-2}$$

- An equation for estimation of the number of impeller cycles which will have occurred at any time is obtained by integration of Eq. 2.

$$\begin{aligned} dI_c / dt &= C_1 e^{kt} \\ \int dI_c &= \int C_1 e^{kt} dt \\ &= C_1 \int_0^t e^{kt} dt \\ &= C_1 (e^{kt}/K) \Big|_0^t \\ &= C_1 (e^{kt}/k - e^{k(0)}/k) \\ &= C_1 (e^{kt}/K - 1/k) \\ &= C_1 / K (e^{kt} - 1) \\ &= C_1 (e^{kt} - 1) / k \end{aligned} \quad (3)$$

Fig. 54 Mask volume versus time (days), continuous function

Equation 3 is an expression for the number of impeller cycles to which the original mask will be subjected at any time (t).

- 1.4 The maximum number of impeller cycles experienced by the original mask during its tank life may be estimated by integration of Eq. 4 with limits zero to infinity (∞).

$$I_{cm} = \int_0^{\infty} C_1 e^{kt} dt, \text{ improper integral}$$

let b = the upper limit of the integral, as b approaches infinity (∞).

$$\begin{aligned} \lim_{b \rightarrow \infty} \int_0^b C_1 e^{kt} dt &= \lim_{b \rightarrow \infty} C_1 \int_0^b e^{kt} - dt \\ I_{cm} &= C_1 \lim_{b \rightarrow \infty} (e^{kt}/k) \Big|_0^b \\ &= C_1 \lim_{b \rightarrow \infty} (e^{kb}/k - e^{k(0)}/k) \\ &= C_1 \lim_{b \rightarrow \infty} (e^{kb}/k - 1/k) \\ &= C_1 \lim_{b \rightarrow \infty} (e^{kb}/k) - C_1 \lim_{b \rightarrow \infty} (1/k) \end{aligned}$$

where $C_1 \lim_{b \rightarrow \infty} (e^{kb}/k) = 0$ by L'Hopital's Rule.

then $I_{cm} = 0 - C_1 \lim_{b \rightarrow \infty} (1/k) = -C_1/k$
therefore,

$$I_{cm} = -C_1/k [\text{cycles} * \text{day/day}]$$

1.4.1 Application of L'Hopital's Rule:^[9]

$$\lim_{b \rightarrow \infty} C_1 e^{kb}/k = 0$$

since the limit converges to zero as (b) increases to infinity, apply L'Hopital's Rule, i.e. take the derivative of e^{kb}/k .

$$\Rightarrow C_1 \lim_{b \rightarrow \infty} k e^{kb}/k = C_1 \lim_{b \rightarrow \infty} e^{kb} = 0.$$

for

$$k = -3.39 \times 10^{-2} \text{ day}^{-1}.$$

Since the subject limit equals zero, all that remains in the derivation of Eq. 4 is $(-1/k)$, multiplied by the constant number of impeller cycles per day, as is shown in para. 1.4.

Assumptions:

- The use of mixers will promote a homogeneous mixture of maskant. Mixers, capable of moving large volumes at low pressure, can thoroughly mix/blend maskant from the initial tank charge with new maskant added to maintain a constant fluid level in the tank.

Fig. 55 Test apparatus

- By estimating the total number of impeller cycles to which maskant will be subjected, one can estimate the length of time the original tank charge of maskant will be resident in the maskant tank. These estimates can then be used to establish an appropriate mask stability test period/apparatus by the maskant vendor.

Test Apparatus (Fig. 55):

Experiment Set Up:

- Place a 3.5l Griffin beaker in a black colored laboratory sink (for color contrast).
- Fill the beaker to over flow (4.95 l capacity when completely full), then insert mixer.
- Set mixer speed at 300 RPM for minimal vortex. Mixer rotational speed selection is dependent upon impeller diameter and type. For this experiment apparatus a Lightnin' Labmaster mixer with a 3.4 in. diameter A310 impeller was selected. The 3.4 in. A310 has a pumping capacity of 28 gal/min (gpm) at 300 RPM.
- Add 50 ml of AC JW4-87 waterborne scribe line sealer, or other colorant, to create opaque white color, (AC JW4-87 Line Sealer was selected because it was within reach—white colored latex paint would have been a good choice too—select any colorant that provides good contrast with the background color).
- Measure flow rate from faucet at beginning and end of test run and used the average flow rate for calculations.

Execution:

- The experiment apparatus was assembled and water flow rate from the faucet determined. The faucet flow was directed into the full beaker of opaque white colored solution. A timer was started as water

from the faucet entered the beaker. As time elapsed the following observations were noted: (a) the color of the solution remained uniform, no stratification occurred as is typical when cold water runs into a container and the intent is to displace whatever is in the container; (b) condensate formed on the sides of the beaker, which complicates determination of when the original solution is completely displaced from the beaker.

2. Results:

- Water flow rate from the faucet was 0.366 gpm.
- At 26 min elapsed time distortion created by the beaker glass and condensate on the glass surface began to obscure the contrast between the black colored lab sink and the solution in the beaker. Therefore the viewing position was changed to directly over the beaker, such that one could view the sink bottom. Distortion was minimal in the new viewing position.
- At 31 min the solution appeared completely clear and the run was stopped. A replicate experiment was set up and executed.
- In the replicate experiment the opaque white color seemed to dissipate between 30 and 34 min. Allowing the water to run through 41 min elapsed time did not seem to make the solution in the beaker any clearer, therefore the experiment run was terminated. The experiment data indicates that with a 0.366 gpm flow rate into the beaker, virtually all of the original solution resident in the beaker had been displaced in approximately **28–34 min**.

3. Calculations/Estimates:

3.1 System Information:

Flow Rate (Usage Rate) from Faucet: 1.385 l/min

Volume of container/tank: 4.95 l

Pumping Capacity of Mixer: 28 gpm (106 l/min)

Coefficient of Use:

$$k = \ln[(4.95 \text{ l} - 1.385 \text{ l/min})/4.95 \text{ l}]$$

$$= -0.328 \text{ min}^{-1}$$

3.2 Mixing Cycles:

$$C_1 = \frac{\text{total pumping capacity (gal/day)}}{\text{tank volume (gal/cycle)}}$$

$$C_1 = \text{cycles/day}$$

$$\Rightarrow C_1 = 106/4.95 [\text{litres} \cdot \text{cycle} / \text{liters} \cdot \text{min}]$$

$$= 21.41 \text{ cycles/min}$$

$$I_{cm} = -C_1 k \quad (4)$$

where I_{cm} = Impeller Cycles, maximum

$$\Rightarrow I_{cm} = -(21.41)/-0.328 [\text{cycles} \cdot \text{min} / \text{min}]$$

$$= 65.27 \text{ total cycles.}$$

3.3 Estimate of maskant time in tank (Note: time base converted to minutes):

$$I_{ct} = C_1 (e^{kt} - 1)/k \quad (3)$$

where

I_c = Impeller Cycles, rate for original tank charge at any time (t), cycles/minute.

C_1 = Average number of impeller cycles occurring each day, for the entire tank volume, cycles/minute.

t = time, minutes

k = coefficient of mask usage, min^{-1}

To estimate time in tank, substitute I_{cm} for I_{ct} in Eq. 3, and solve for (t).

$$65.27 = 21.41(ekt - 1)/k$$

$$65.27(k)/21.41 = ekt - 1$$

$$(65.27(k)/21.41) + 1 = ekt$$

$$\ln[(65.27(k)/21.41) + 1] = kt$$

$$t = (\ln[(65.27(k)/21.41) + 1])/k$$

$$t = (\ln[(65.27(-0.328)/21.41) + 1])/-0.328$$

$$[\text{cycles} \cdot \text{min} \cdot \text{min} / \text{cycles} \cdot \text{min}]$$

$$t = \mathbf{29.3 \text{ min}}$$

The estimate for maskant “time in tank”, and the results from the experiment, given the stated opportunities for experiment error, are virtually the same. Therefore, it is concluded that the underlying assumptions, or hypothesis about the mixer based tank design are correct.

4. Discussion regarding the mathematical estimate of Impeller Cycles (I_{cm} and I_{ct}) and Time in Tank, (t).

4.1 Equation 3 is asymptotic like Eq. 2 from which Eq. 3 is derived. A proof will not be attempted here, but a chart of Eq. 3 with the parameters outlined in para. 3 demonstrates the situation sufficiently:

Impeller Cycles where $k = -0.328$, $C_1 = 21.41$ (Fig. 56)

Fig. 56 Impeller cycles versus time (min)

The chart demonstrates that possible solutions for Eq. 3 fall between 21 min elapsed time and infinity (∞). However, a review of I_{ct} calculations, which are the basis for the chart indicate the best estimate, or at least an adequate estimate, for (t) is between 25 and 30 min.

elapsed time (t)	I_{ct} , Impeller Cycles
5	52.61
10	62.82
15	64.8
20	65.18
25	65.256
30	65.271
35	65.274
40	65.2743
45	65.2744

- 4.2 In para. 3, note that estimates for C_1 and I_{cm} are carried to 2 decimal places. The estimate for (k) is carried to three decimal places. The convention for significant digits was ignored for C_1 and I_{cm} estimates. However, the estimate for (t) is rounded to the least number of significant digits found in the information defining system parameters.
- 4.3 The SOLVE algorithms available with most any scientific calculators may also be used to find and estimate for (t) , as outlined in para. 3. SOLVE algorithms require that the equation be re-arranged as follows:

$$I_{ct} = C_1(e^{kt} - 1)/k$$

$$0 = [C_1(e^{kt} - 1)/k] / I_{ct} \quad (3)$$

The SOLVE algorithm must then find a value for (t) that makes the mathematical statement true. Since computing devices such as a scientific calculator carry calculations to 8–16 decimal places the solution derived by a SOLVE algorithm could be significantly different, i.e. larger than the result calculated in para. 3. Based on the chart, the answer derived by a SOLVE algorithm would be correct such that it makes the mathematical statement, $0 = [C_1(e^{kt} - 1)]/k / I_{ct}$ true. However, in a practical sense, the solution for (t) derived by the SOLVE algorithm is not the answer. For example, the observations described in para. 2, and the calculation outlined in para. 3 provide the same answer in practical terms. The SOLVE algorithm available on the authors Hewlett-Packard 15C Scientific Calculator found that (t) must equal 71.075 min for the statement $0 = [C_1(e^{kt} - 1)]/k / I_{ct}$ to be true.

- 4.4 A suggested practice for those testing maskant stability would be to estimate (t) as outlined in para. 3, then apply a safety factor of 3. Hence, the stability test would run approximately three times longer than would be expected for maskant resident in the production tank.

APPENDIX B

Maskant Surface Coverage Calculation and Maskant use Estimation.

SURFACE COVERAGE, CHEM-MILL MASKANTS

Suppliers always report the solids content of a coating as % by weight, and sometimes they will include solids content as % by volume. To determine the area that a particular coating will cover, solids by % weight must be converted to a % by volume. Calculation of coating coverage is included as reference for those instances when the supplier does not include solids content as % by volume. *Note:* the unit for coating coverage is sq ft – mil/gal i.e. the area covered by 1 gal of material, dry coating thickness 1mil, (0.001 in.).

Solvent maskant may be purchased as a concentrate. As per the supplier's tech data sheet the density is 12.4 lb/gal. However, as per the suppliers technical data sheet, 55 gal of maskant must be thinned with 14 gal of perchloroethylene, hence the weight of the perchloroethylene must be added; then the new total weight divided by the total gallons, mask concentrate plus thinner.

$\times$	12.4 lb/gal mask	13.47 lb/galperc
	55 gal	14 gal
	682 lb mask	188.58 lbperc
	682 lb mask	55 gal mask
+	188.58 lbperc	14 gal perc
	870.58 lb total	69 gal total
	870.58 lb mask and perc	
	/ 9 gal mask and perc	
	12.62 lb gal.	

Adding perc to thin the mask concentrate effects the weight solids. Therefore, the weight solids must be recalculated. The MSDS sheet reports weight solids of 20%. The suppliers technical data sheet reports a weight solids of 25% before thinning. Check:

	55 gal mask con.
	12.4 lb/gal
$\times$	0.25 wt% solids
	170.5 lb solids

$$\begin{array}{r} 170.5 \text{ lb solids} \\ / \quad 870.58 \text{ lb mask and perc} \\ \hline 0.2 \text{ wt\% solids} \end{array}$$

Coverage: Coating capability of 1 gal of solvent mask.

$$\begin{array}{r} 12.62 \text{ lb mask} \\ \times \quad 0.2 \text{ wt\% solids} \\ \hline 2.471 \text{ lb solids} \\ \\ 12.62 \text{ lb mask} \\ - \quad 2.471 \text{ lb solids} \\ \hline 10.1461 \text{ lb solvent} \\ / \quad 13.47 \text{ lb perc} \\ \times \quad 100 \\ \hline 75.32 \text{ vol \% perc. (gal)} \end{array}$$

$$\begin{array}{r} 1 \% \\ - \quad 0.7532 \text{ vol. perc solvent} \\ \times \quad 100 \\ \hline 24.68 \text{ vol \% solids} \end{array}$$

$$\begin{array}{r} 231 \text{ in(3)/gal} \\ \times \quad 0.2468 \text{ vol. solids} \\ \hline 57 \text{ in(3)/gal.} \end{array}$$

$$\begin{array}{r} 0.001 \text{ in.} = 1 \text{ mil} \\ \times \quad 144 \text{ in(2)/ft(2)} \\ \hline 0.144 \text{ in(3)/ft(2)} \end{array}$$

$$\begin{array}{r} 57 \text{ in(3)/gal.} \\ / \quad 0.144 \text{ in(3)/ft(2)} \\ \hline 396 \text{ ft(2)-mil/gallon} \end{array}$$

Thus, the solvent mask covers 396 sq ft—mil gal as used. Note, the technical data sheet lists coverage as 500 sq ft/gal, which, is correct for the concentrate form, however, the maskant is thinned before use and therefore covers less area.

Metal Surface Coated Per Year

- Volume of maskant purchased = 4091 gal
- Volume of perc added to dilute maskant = 1043 gal
- Area, (sq) ft, that 1 gal of solvent mask can cover with a 1 mil thick coating = 391 sqft
- Average film thickness = 15 mil
- Area covered by 1 gal of solvent mask @ 15 mil:

$$\begin{array}{r} 396 \text{ sq ft - mil/gal} \\ / \quad 15 \text{ mil} \\ \hline 26.39 \text{ sq ft/gal, actual coverage} \end{array}$$

$$\begin{array}{r} 4091 \text{ gal mask purchased} \\ + \quad 1043 \text{ gal perc added} \\ \hline 5135 \text{ total mask and perc used} \\ \times \quad 26.39 \text{ sq ft/gal, atual coverage} \\ \hline 135,500 \text{ sq ft metal coated} \end{array}$$

Surface Coverage and Volume Estimate, Waterborne Maskant

The maskant technical data sheet reports density of 10.1 lb/gal and 615 sq ft—mil gal coverage, which, is correct if the maskant is maintained at 49.1 wt% solids

$$\begin{array}{r} 10 \text{ lb/gal mask} \\ \times \quad 0.45 \text{ wt\% solids} \\ \hline 4.5 \text{ lb solids} \end{array}$$

$$\begin{array}{r} 10.1 \text{ lb/gal mask} \\ - \quad 4.5 \text{ lb solids} \\ \hline 5.6 \text{ lb water/gal mask} \\ / \quad 8.34 \text{ lb/gal water} \\ \hline 0.6715 \text{ vol\% water, (gal)} \end{array}$$

$$\begin{array}{r} 1 \% \\ - \quad 0.6715 \% \text{ water} \\ \hline 0.3285 \text{ vol \% solids} \end{array}$$

$$\begin{array}{r} 231 \text{ in(3)/gal} \\ \times \quad 0.3285 \text{ vol \% solids} \\ \hline 75.89 \text{ in(3)/gal} \end{array}$$

$$\begin{array}{r} 0.001 \text{ in.} = 1 \text{ mil} \\ \times \quad 144 \text{ in(2)/ft(2)} \\ \hline 0.144 \text{ in(3)/ft(2)} \end{array}$$

$$\begin{array}{r} 75.89 \text{ in(3)/gal} \\ / \quad 0.144 \text{ in(3)/ft(2)} \\ \hline 527 \text{ ft(2) mil/gal} \end{array}$$

Cost of Waterborne Maskant

- Metal surface area coated = 135,500 sqft
- Optimum coating thickness = 18 mil
- Waterborne maskant coverage = 527 sqft —mil/gal

$$\begin{array}{r} 527 \text{ sq ft mil/gal} \\ 18 \text{ mil coating} \\ / \quad 29.28 \text{ sq ft covered by each gallon of maskant} \\ \hline \text{with a 18 mil thick dry film} \\ 135,500 \text{ sq ft surface coated} \\ / \quad 29.28 \text{ sq ft/gal @ 18mil} \\ \hline 4628 \text{ gal of waterborne maskant required.} \end{array}$$

APPENDIX C

Derivation of tank lining erosion equation.

1. Derivation of etch rate formula for plate or sheet stock samples. Assume that equal amounts of material are removed from all surfaces. The density of sample material must be known. The apparent density may be used, or an accepted value for the particular alloy may also be used.
2. The volume of the plate or sheet stock is defined as follows (Ref. Fig. 48)

$$V = (x)(y)(z)$$

A partial derivative may be used to determine the change in sample volume relative to the changes in the samples physical measurements. Thus, the change in the sample volume (dV) is defined by

$$dV = (\partial V / \partial x)dx + (\partial V / \partial y)dy + (\partial V / \partial z)dz; \partial V / \partial x = yz, \text{ etc.}$$

As stated, equal amounts of material are assumed to be removed from all surfaces. Thus, a total of six surfaces, two xy , two xz and two yz , are reduced by chemical etching.

Therefore, the equation defining the change in volume becomes

$$dV = 2yzdx + 2xzdy + 2xydz$$

The change in volume (dV) can also be defined as the quotient of the change in sample mass (dM) and the material density (ρ), or

$$dV = dM / \rho$$

Since all sample dimensions are changing by an equal distance, let that distance be defined as (ds). Thus,

$$ds = dx = dy = dz.$$

With appropriate substitutions the change in sample volume becomes

$$dM / \rho = 2yzdx + 2xzdy + 2xydz$$

Therefore,

$$ds = dM / [2\rho(yz + xz + xy)]$$

The new expression for (ds) describes the change in sample dimensions for each surface for a change in sample mass. Elapsed time for the test is Δt (years), then the apparent etch rate is $ds/\Delta t$.

3. Error estimation: error in etch rate calculation is estimated by adding all error associated with sample dimension measurement and mass measurement. Balance scale accuracy is ± 1.0 mg for 0–10 g, ± 1.5 mg for 10–100 g and ± 2.5 mg for 100–1000 g. Caliper accuracy is ± 0.002 in. and dial indicator accuracy is ± 0.002 in. The unitless ratio of error in etch distance (δds) and the distance calculated (ds) is

$$\delta ds / ds = \delta dM / dM + \delta A / A$$

where

dM / dM = error in mass measurement

$\delta A / A$ = cumulative error in measurements for determination of surface area

$$\delta dM = \delta M_1 + \delta M_2$$

$$= (0.0025 + 0.0025)g$$

$$\delta dM = 0.005g$$

$$\delta A / A = \delta A_1 / A_1 + \delta A_2 / A_2 + \delta A_3 / A_3$$

where,

$$\delta A_1 / A_1 = (0.05)w + (0.002) t^*$$

$$\delta A_2 / A_2 = \delta l / l + \delta t / t = (0.05) / l + (0.002) / t$$

$$\delta A_3 / A_3 = \delta l / l + \delta w / w = (0.05) / l + (0.05) / w$$

Computer Vision for Fault Detection in Aluminum Castings

Domingo Mery

Pontificia Universidad Catolica de Chile, Santiago de Chile, Chile

Abstract

Castings produced for the automotive industry are considered the important components for overall roadworthiness. To ensure the safety of construction, it is necessary to check every part thoroughly using nondestructive testing. X-ray testing rapidly became the accepted way for controlling the quality of die cast pieces. In this article, the fundamental principles of the automated detection of casting discontinuities are explained. A general computer vision inspection schema is presented, and several methods that have appeared in the literature in the past 30 years were explained showing the development of this sector in the areas of industry and academia.

Keywords: Aluminum castings; Computer vision; Image processing; Image analysis; Pattern recognition; Quality control; X-ray testing.

INTRODUCTION

To ensure safety in the construction of important metallic components for roadworthiness, it is necessary to check every component thoroughly using nondestructive testing. In the past few decades, X-ray testing has been adopted as the principal nondestructive testing method to identify the defects within a component that are undetectable to the naked eye. Nowadays, modern computer vision techniques, such as deep learning^[1] and sparse representations,^[2] are opening new avenues in automatic object recognition in optical images. These techniques have been broadly used in object and texture recognition by the computer vision community with promising results in optical images. In this article, we present a general overview of image processing approaches that have been used in X-ray testing for the inspection of aluminum castings.

Light-alloy castings produced for the automotive industry, such as wheel rims, steering knuckles, and steering gear boxes, are considered the important components for overall roadworthiness. Nonhomogeneous regions can be formed within the work piece in the production process. These are manifested, for example, by bubble-shaped voids, fractures, inclusions, or slag formation. To ensure the safety of construction, it is necessary to check every part thoroughly using X-ray testing. In casting inspection, automated X-ray systems have not only raised quality, through repeated objective inspections and improved processes, but also increased productivity and consistency by reducing labor costs. Some examples are illustrated in Fig. 1.

X-Ray testing is one of the more accepted ways for examining an object without destroying it.^[3] The purpose of this nondestructive method is to detect or recognize certain parts of interest that are located inside a test object and are thus not detectable to the naked eye. The material defects occurring in the casting process such as cavity, gas, inclusion, and sponge must be detected to satisfy the security requirements; consequently, it is necessary to check 100% of the parts.

The principal aspects of an X-ray testing system are illustrated in Fig. 2. Typically, it comprises the following steps:

- The test object is located in the desired position using a manipulator.
- The X-ray source generates X-rays that pass through the test object.
- The X-rays are detected and converted by a flat panel in order to obtain a digital X-ray image.
- Computer vision algorithms are used to evaluate the X-ray image.

In recent years, flat detectors made of amorphous silicon have been widely used as image sensors in some industrial inspection systems.^[4] In these detectors, the energy from the X-ray is converted directly into an electrical signal by a semiconductor (without an image intensifier).

In the computer-aided inspection of castings, our aim is to identify discontinuities automatically using computer vision techniques. The general automated inspection process, presented in Fig. 3, consists of image formation, pre-processing, segmentation, feature extraction, detection/classification, and multiple view analysis. Some approaches

Fig. 1 Real defects in X-ray images of wheels

Fig. 2 X-ray testing system. The image acquisition system is based on flat panels. In this example, an aluminum wheel is inspected using a manipulator

Fig. 3 Schematic diagram of an automated X-ray testing stand

use pattern recognition and multiple view techniques. A general schema follows the below-mentioned six steps:

1. *Image formation*: An X-ray image of the casting under test is taken and stored in the computer. The eye is only capable of resolving around 40 gray levels;^[5] however, for the detection of discontinuities in aluminum castings, gray-level resolution must be a minimum of 2^8 levels. In some applications, 2^{16} gray levels are used, which allow one to evaluate both very dark and very bright regions in the same image.
2. *Image preprocessing*: The quality of the X-ray image is improved in order to enhance the details of the X-ray image. Usually, the preprocessing techniques are used to remove noise, enhance contrast, correct the shading effect, and restore blur deformation.
3. *Image segmentation*: The digital images are divided into disjoint regions with the purpose of separating the parts of interest from the rest of the scene. The idea is to segment those regions that correspond to the defects of the specimen.
4. *Feature extraction*: Although some structural parts of the object could be erroneously segmented as defective regions in the previous step, they are denoted as hypothetical defects. Subsequently, additional steps are required to eliminate the false alarms of the hypothetical defects. The first of these steps is feature extraction, which is centered principally around the measurement of geometric properties and on the intensity characteristics of regions. It is important to know which features provide information about discontinuities. With this end in view, a feature selection is carried out to find those features that best describe discontinuities, eliminating, for example, the features that are correlated or provide no information whatsoever.
5. *Detection/classification*: The extracted (and selected) features of each region are analyzed in order to detect or classify the existing defects. We will differentiate between the detection of discontinuities and the classification of discontinuities. Detection corresponds to a binary classification, because in the detection problem, the classes that exist are only two: “discontinuities”

(defects) or “regular structures” (no defects), whereas the recognition of the type of discontinuity (e.g., voids, cracks, bubbles, inclusions, and slags) is known as the classification of discontinuity types.

6. *Multiple view analysis*: Some methods use an additional step based on multiple view geometry. The key idea of the multiple view analysis is to gain more information about a test object by analyzing multiple views taken at different viewpoints. Multiple view analysis is a useful and powerful alternative for examining complex objects where uncertainty can lead to misinterpretation, because two or more views of the same object taken from different viewpoints can be used to confirm and improve the diagnostic done by analyzing only one image.

In this article, the use of computer vision as a tool in the automated radiosopic inspection of aluminum die castings is discussed. In “State of the Art” section, the state of the art is presented. In “X-ray Image Processing” section, image processing techniques used in this field are discussed. In “X-ray Image Representation” section, different methods that can be used to represent the image information of the castings are explained. In “Multiple View Analysis” section, an overview of the multiple view analysis is given. Finally, in “Conclusions” section, concluding remarks are presented.^a

STATE OF THE ART

Different methods for the automated detection of casting discontinuities using computer vision have been described in the literature over the past 30 years.^[3] One can see that different approaches for this task can be divided into three groups:^[7,8]

1. *Reference methods*: In these methods, it is necessary to take still images at selected programmed inspection positions. A test image is then compared with the reference image. If a significant difference is identified, the test piece is classified as defective.
2. *Methods without a priori knowledge of the structure*: These methods use pattern recognition, expert systems, artificial neural networks, general filters, or multiple view analyses to make them independent of the position and structure of the test piece.
3. *Computed tomography*: This method uses computed tomography to make a reconstruction of the cast piece and therefore detect discontinuities.

^aWe developed Matlab Toolbox called Xvis Toolbox (available online at <http://dmery.ing.puc.cl/index.php/book/xvis/>), with around 150 functions for computer vision in X-ray testing. Moreover, there are around 20,000 X-ray images on the GDX ray database^[59] (available online at <http://dmery.ing.puc.cl/index.php/material/gdxdxray/>) that can be used to test different algorithms and codes. The X-ray images of this work belong to GDX ray.

A selection of recent approaches is summarized in Table 1. In general, they use classical image processing and pattern recognition techniques with a single view or multiples views, where decision is made by analyzing the correspondence among the views.

Nowadays, modern computer vision techniques, such as deep learning^[1,21,22] and sparse representations,^[2,23] are opening new avenues in automatic object recognition in optical images. These techniques have been broadly used in object and texture recognition by the computer vision community with promising results in optical images.

X-RAY IMAGE PROCESSING

Image processing manipulates a digital image in order to obtain a new digital image; in this process, the input is an image and the output is another image. A typical example is *segmentation* as shown in Fig. 4, where the input is a grayscale image that contains a defect and the output is a binary image where the pixels that belong to the defect are detected. We distinguish image processing from image analysis, in which the output is rather an interpretation, a recognition, or a measurement of the input image.

In this section, the following image processing techniques that are used in X-ray testing are covered:

- *Image preprocessing*: The quality of the X-ray image is improved in order to enhance its details.
- *Image filtering*: It is mainly used to remove noise and detect high-frequency details of the X-ray image.

Fig. 4 Image processing: input is digital image $\mathbf{X}$ and output is digital image $\mathbf{Y}$

- *Edge detection:* The details of the images can be highlighted by detecting the boundaries of the objects of the X-ray image.
- *Image segmentation:* Regions of interest of the X-ray image are identified and isolated from their surroundings.
- *Image restoration:* This involves recovering details in blurred images.

In this section, an overview of these five techniques is provided. Methodologies and principles will be outlined, and some application examples followed by limitations to the applicability of the used methodologies will be presented.

In the image processing methodology, a continuous image f is defined in a coordinate system (x, y) . Image f is digitalized. The obtained image is a digital image that is stored in matrix $\mathbf{X}$ of size $M \times N$ pixels. The gray value of pixel (i, j) of image $\mathbf{X}$ is $X(i, j)$. Image $\mathbf{X}$ is processed digitally. The output image of this process is image $\mathbf{Y}$, usually a matrix of the same size of $\mathbf{X}$. In this example, the output is a binary image, which means $Y(i, j)$ is “1” (white) and “0” (black). Image $\mathbf{Y}$ corresponds to the segmentation of a defect in an aluminum casting (the *object of interest* in this example).

Image Preprocessing

The X-ray image taken must be preprocessed to improve the quality of the image before it is analyzed. In this section, preprocessing techniques that can remove noise, enhance contrast, correct the shading effect, and restore blur deformation in X-ray images will be discussed.

Noise Removal

Noise in an X-ray image can prove a significant source of image degradation and must be taken into account during image processing and analysis. In an X-ray imaging system, *photon noise* occurs given the quantum nature of

X-rays. If we have a system that receives μ photons per pixel in a time ΔT . On average, the number of photons striking any particular pixel in any time ΔT will be random. At low levels, however, the noise follows a Poisson law, characterized by the probability:

$$p(x | \mu) = \frac{e^{-\mu} \mu^x}{x!} \quad (1)$$

to obtain a value x of photons given its average μ photons in a time ΔT . The standard deviation of this distribution is equal to the square root of the mean^b. This means that the photon noise amplitude is signal dependent.

Integration (or averaging) is used to remove X-ray image noise. This technique requires n stationary X-ray images. It computes the filtered image as follows:

$$Y(i, j) = \frac{1}{n} \sum_{k=1}^n X_k(i, j) \quad (2)$$

where $X_k(i, j)$ is pixel (i, j) of the k th stationary image, and $Y(i, j)$ is the corresponding pixel of the filtered image.

In this technique, the X-ray image noise is modeled using two components: the stationary component (that is constant throughout the n images) and the noise component (that varies from one image to the next). If the noise component has zero mean, by averaging the n images, the stationary component is unchanged, whereas the noise pattern decreases by increasing n . Integrating n stationary X-ray images improves the signal-to-noise ratio by a factor of $\sqrt{n}$.^[5,24]

The effect of image integration is illustrated in Figs. 5 and 6, which uses n stationary images of an aluminum casting and shows the improvement in the quality of the X-ray image. The larger the number of stationary images n , the better the improvement. Normally, between 10 and 16 stationary images are taken ($10 \leq n \leq 16$).

^bAt high levels, the Poisson distribution approaches the Gaussian with a standard deviation equal to the square root of the mean: $\sigma = \sqrt{\mu}$

Fig. 5 Noise removal after an averaging of n frames. The noise is reduced by factor $\sqrt{n}$

Fig. 6 Noise removal of an X-ray image of a casting after an averaging of 32 frames. (Left) One of the 32 images (top) and a filtered image (bottom). (Right) Row 140 of each image where two defects are present. The reader can see how difficult it is to distinguish the defects in the original image (without filtering)

Contrast Enhancement

The gray values in some X-ray images lie in a relatively narrow range of the grayscale. In this case, enhancing the contrast will amplify the differences in the gray values of the image.

We compute the gray value histogram to investigate how an X-ray image uses the grayscale. The function summarizes the gray value information of an X-ray image. The histogram is a function $h(x)$ that denotes the number of pixels in the X-ray image having a gray value equal to x . Figure 7 shows how each histogram represents the distribution of gray values in the X-ray images.

A transformation can be applied to modify the distribution of gray values in the X-ray image. Simple contrast enhancement can be achieved if we use a linear transformation that sets the minimal and maximal gray values of the X-ray image to the minimal and maximal gray values of the grayscale, respectively. Thus, the histogram is expanded to occupy the full range of the grayscale. Mathematically, for

a scale between 0 and 255, this transformation is expressed as $\mathbf{Y} = 255\mathbf{X}_0$, with

$$X_0(i, j) = \frac{X(i, j) - x_{\min}}{x_{\max} - x_{\min}} \quad (3)$$

where $x_{\min}$ and $x_{\max}$ denote the minimal and maximal gray values, respectively, of the input X-ray image $\mathbf{X}$. The output image is stored in matrix $\mathbf{Y}$. Figure 7b shows the result of the transformation applied to the X-ray image in Fig. 7a. How the gray values expand from “0” to “255” can be observed in the histogram of the enhanced X-ray image. The mapping is linear and means that a gray value equal to $\frac{1}{2}(x_{\max} - x_{\min})$ will be mapped to $255/2$. This linear transformation is illustrated in Fig. 8a, where the abscissa is the input gray value and the ordinate is the output gray value.

In a similar fashion, gray input image values can be mapped using a nonlinear transformation $y = f(x)$, illustrated in Fig. 8b and c, the results of which are shown in

Fig. 7 Contrast enhancement: (a) original image; (b) linear transformation ($\gamma = 1$); (c) nonlinear transformation ($\gamma = 2$); (d) nonlinear transformation ($\gamma = 1/2$), and (e) gray values uniformly distributed

Fig. 8 Plots showing different transformations of the gray values: (a) linear transformation ($\gamma = 1$); (b) nonlinear transformation with $\gamma > 1$; (c) nonlinear transformation with $\gamma < 1$

Fig. 7c and d, respectively. Here, x and y are the gray values of the input and output images, respectively. The nonlinear transformation is usually performed with a γ correction.^[25] In these examples, if $\gamma > 1$, the mapping is weighted toward darker output values, and if $\gamma < 1$, the mapping is weighted toward brighter output values. Gamma transformation can be expressed as $\mathbf{Y} = 255\mathbf{Y}_0$, with

$$Y_0(i, j) = \begin{cases} 0 & \text{for } X(i, j) < x_{\min} \\ (X_0(i, j))^\gamma & x_{\min} \leq X(i, j) \leq x_{\max} \\ 1 & X(i, j) > x_{\max} \end{cases} \quad (4)$$

where $X_0(i, j)$ is defined in Eq. 3.

Finally, a contrast enhancement equalizing the histogram is presented. Here, the gray value distribution can be altered in order to obtain a desired histogram. A typical equalization corresponds to the uniform histogram as shown in Fig. 7e. We see that the number of pixels in the X-ray image for each gray value is constant. In the example

of Fig. 9, there are zones of an X-ray image of a casting with poor contrast. How the defects can be distinguishable can be seen using the mentioned approach.

Shading Correction

A decrease in the angular intensity in the projection of X-rays causes low spatial frequency variations in X-ray images.^[24,26] An example is illustrated in Fig. 10a, which shows an X-ray image of an aluminum plate with holes in it. Although the plate is of a constant thickness, we would expect to see a constant gray value for the aluminum part and another constant gray value for the holes. In fact, the X-ray image is darker at the corners. This deficiency can be overcome by using a linear shading correction.

In this technique, we take two reference images as shown in Fig. 12: the first one, r_1 of a thin plate, and the second one, r_2 of a thick plate. i_1 and i_2 are defined as the ideal gray values for the first and second images, respectively. From r_1 , r_2 , i_1 , and i_2 , offset and gain correction matrices a and b are calculated assuming a linear

Fig. 9 Contrast enhancement by uniforming a histogram of the selected area

Fig. 10 Shading correction: (a) original image; (b) image after shading correction. The corresponding gray value profiles of row number 130 are shown above the images

transformation between the original X-ray image x and the corrected X-ray image y :

$$Y(i, j) = a(i, j) \cdot X(i, j) + b(i, j), \quad (5)$$

where the offset and gain matrices are computed as follows:

$$a(i, j) = \frac{i_2 - i_1}{r_2(i, j) - r_1(i, j)} \quad (6)$$

$$b(i, j) = i_1 - r_1(i, j) \cdot a(i, j).$$

An example of this technique is illustrated in Fig. 10b. In this case, we obtain only two gray values (with noise): one for the aluminum part and another for the holes of the plate. In the example of Fig. 11, we simulate image $\mathbf{X}$ (a plate with a square cavity). In addition, we simulate X-ray images r_1 (a thin plate) and r_2 (a thick plate) as illustrated

in Fig. 12. The correction is evident: the appearance of the background is homogeneous, whereas the square is more distinguishable.

Image Filtering

2D image filtering is performed in digital image processing using a small neighborhood of a pixel $X(i, j)$ in an input image to produce a new gray value $Y(i, j)$ in the output image, as shown in Fig. 13. A *filter mask* defines the input pixels to be processed by an *operator* f . The resulting value is the output pixel. The output for the entire image is obtained by shifting the mask over the input image. Mathematically, the image filtering is expressed as follows:

$$Y(i, j) = f[\underbrace{X(i-p, j-p), \dots, X(i, j), \dots, X(i+p, j+p)}_{\text{Input pixels}}], \quad (7)$$

Fig. 11 Simulation of shading correction: (left) X-ray image for a plate with a square cavity (**X**); (right) corrected image (**Y**)

Fig. 12 Shading correction: a) X-ray image for a thin plate; b) X-ray image for a thick plate. Ideal X-ray images have a constant gray value

Fig. 13 Image filtering

for $i = p + 1 \dots M - p$ and $j = p + 1 \dots N - p$, where M and N are the number of rows and columns of the input and output images, respectively. The size of the filter mask is, in this case, $(2p + 1) \times (2p + 1)$. The operator f can be linear or nonlinear. In this section, the most important linear and nonlinear filters for X-ray testing are outlined.

Linear Filtering

The operator f is linear, if the resulting value $Y(i, j)$ is calculated as a linear combination of the input pixels:

$$Y(i, j) = \sum_{m=-p}^p \sum_{n=-p}^p h(m, n) \cdot X(i - m, j - n), \quad (8)$$

where $\mathbf{h}$ is called the *convolution mask*. The elements of $\mathbf{h}$ weight the input pixels. The convolution of an image $\mathbf{X}$ with a mask $\mathbf{h}$ can be written as follows:

$$\mathbf{Y} = \mathbf{X} * \mathbf{h}. \quad (9)$$

Averaging is a simple example of linear filtering. For a 3×3 neighborhood, the convolution mask is

$$\mathbf{h} = \frac{1}{9} \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

Gaussian mask can be used as well:

$$h(m,n) = \frac{1}{2\pi\sigma^2} \cdot e^{-\frac{m^2+n^2}{2\sigma^2}} \quad (10)$$

Scale factor $1/(2\pi\sigma^2)$ ensures $\sum_{m,n} h(m,n) = 1$ over all elements of h .

A common application of filtering in X-ray testing is defect detection. Filtering out defects detected in an X-ray image will provide a reference *defect-free* image. The defects are detected by finding deviations in the original image from the reference image. The problem is how one can generate a defect-free image from the original X-ray image. Assuming that the defects will be smaller than the regular structure of the test piece, one can use a low-pass filter that does not consider the high-frequency components of the image. However, if a linear filter is used for this task, the edges of the regular structure of the specimen are not necessarily preserved, and many false alarms are raised at the edges of regular structures. Consequently, a nonlinear filter is commonly used.

Nonlinear Filtering

In order to avoid the above-mentioned problems of linear filters, nonlinear filters are used. Defect discrimination can be performed with a *median filter*. The median filter is a ranking operator (and thus nonlinear) where the output value is the middle value of the input values ordered in a rising sequence.^[27] For an even number of input numbers,

the median value is the arithmetic mean of the two middle values.

The application of a median filter is useful for generating the reference image because it smooths noise yet preserves sharp edges, whereas other linear low-pass filters blur such edges (see a comparison with linear filters in Fig. 14). Hence, it follows that small defects can be suppressed, whereas regular structures are preserved. Figure 15 shows this phenomenon for an ID example. The input signal x is filtered using a median filter with nine input elements, and the resulting signal is y . We can see that structures of length $n > 4$ cannot be eliminated. The third column shows the detection $x-y$. Large structures of $n \geq 5$ are not detected, as presented in the past two cases.

If the background captured by the median filter is constant, foreground structures could be suppressed if the number of values belonging to the structure is less than one-half of the input value to the filter. This characteristic is utilized to suppress the defect structures and to preserve the design features of the test piece in the image.

An example for the application of a median filter on 2D signals (images) is shown in Fig. 16 and includes different structures and mask sizes compared to the effects of two linear low-pass filters. One can appreciate that only the median filter manages to suppress the relatively small structures completely, whereas the large patterns retain their gray values and sharp edges.

The goal of the background image function, therefore, is to create a defect-free image from the test image. A real example is shown in Fig. 17. In this example, from an original X-ray image $\mathbf{X}$, we generate a filtered image $\mathbf{Y}$ and a difference image $|\mathbf{X} - \mathbf{Y}|$. By setting a threshold, we obtain a binary image whose pixels are “1” (or white), where the gray values in the difference image are greater than the selected threshold. Finally, we eliminate very small regions. The remaining pixels correspond to the detected flaws.

In the example of Fig. 17, we detect small defects of an aluminum wheel. First, a reference defect-free image is estimated from the original image itself using median filtering. Second, the difference between the original and reference images is computed. Finally, defects are detected when the difference in gray values is high enough and the size of the detected region is large enough.

Fig. 14 Example of filtering of (a) an X-ray image of 400×400 pixels using (b) arithmetic, (c) Gaussian, and (d) median filters with a mask of 15×15 pixels

Fig. 15 Median filter application on a 1D signal x . The filtered signal is y (the size of the median mask is 9). Structures of length n less than $9/2$ are eliminated in y . This filter can be used to detect small structures ($n \leq 4$)

Fig. 16 Median filter application on an $n \times n$ structure using an $m \times m$ quadratic mask compared to average and Gauss low-pass filter application

Edge Detection

In this section, we will study how the *edges* of an X-ray image can be detected. The edges correspond to the pixels of the image in which the gray values change significantly over a short distance.^[5] Although edges are discontinuities in the intensity of the X-ray image, they are normally estimated by maximizing the gradient of the image. Edge detection image corresponds to a binary image (of the same size of the X-ray image), where a pixel is “1” if it belongs to an edge; otherwise it is “0,” as shown in Fig. 18. Before we begin a more detailed description of edge detection, it is worthwhile to highlight some aspects of its relevance in the analysis of X-ray images.

The edges of an X-ray image should show the boundary of objects: boundaries of defects in control quality of aluminum castings, boundaries of the weld in welding inspection, and boundaries of objects in baggage screening (Fig. 18). Thus, the input X-ray image is transformed into a binary image that shows the structural properties of the X-ray image. The key idea is to detect objects of interest, such as defects in case of quality control or threatening objects in case of baggage screening, based on the information provided by edge detection.

In this section, we will review some basic edge detection techniques that have been used in X-ray testing: gradient estimation (“Gradient Estimation” section), Laplacian of Gaussian (LoG; “Laplacian of Gaussian” section), and Canny (“Canny Edge Detector” section). Segmentation techniques based on edge detection will be outlined in “Segmentation” section.

Gradient Estimation

The gradient for a 1D function $f(x)$ is defined by

$$f'(x) = \frac{\partial f}{\partial x} = \lim_{\Delta x \rightarrow 0} \frac{f(x + \Delta x) - f(x)}{\Delta x} \quad (11)$$

and for a 2D function, $f(x, y)$ is defined by a vector of two elements, one in the x direction and another in the y direction:

$$\nabla f(x, y) = \left[\frac{\partial f}{\partial x}, \frac{\partial f}{\partial y} \right]. \quad (12)$$

In digital images, after digitalization of $f(x, y)$, however, the corresponding Δx or Δy values cannot be less than one

pixel. A simple way to compute the gradient of image $\mathbf{X}$ in the i and j directions can be respectively:

$$G_i(i, j) = X(i + 1, j) - X(i, j)$$

$$G_j(i, j) = X(i, j + 1) - X(i, j). \quad (13)$$

Thus, the magnitude of the gradient can be computed as

$$G(i, j) = \sqrt{(G_i(i, j))^2 + (G_j(i, j))^2} \quad (14)$$

and the direction of the gradient as

$$A(i, j) = \arctan \frac{G_j(i, j)}{G_i(i, j)}. \quad (15)$$

In this formulation, gradient images $\mathbf{G}_i$ and $\mathbf{G}_j$ can be easily calculated by convolution (Eq. 9). Thus,

$$\mathbf{G}_i = \mathbf{X} * \mathbf{h}^T \quad \text{and} \quad \mathbf{G}_j = \mathbf{X} * \mathbf{h}. \quad (16)$$

where $\mathbf{h}$ is the mask used to compute the gradient in horizontal direction. For instance, if we compute the gradient using the simple way (Eq. 13), we can use $\mathbf{h} = [-1 \ 1]$ in Eq. 16. Nevertheless, for noisy images, larger masks are suggested for Eq. 16. Sobel and Prewitt masks are commonly used in image processing.^[27] They are defined as follows:

$$\mathbf{h}_{\text{Sobel}} = \begin{bmatrix} -1 & 0 & +1 \\ -2 & 0 & +2 \\ -1 & 0 & +1 \end{bmatrix} \quad (17)$$

$$\mathbf{h}_{\text{Prewitt}} = \begin{bmatrix} -1 & 0 & +1 \\ -1 & 0 & +1 \\ -1 & 0 & +1 \end{bmatrix} \quad (18)$$

For severe noises, it is recommended to use Gaussian filtering before applying gradient operators. Since Gaussian and gradient operations are linear, the Gaussian gradient operator can be defined by taking the derivative of the Gaussian (Eq. 10):

$$\mathbf{h}_{\text{Gauss}}(m, n) = m \cdot e^{-\frac{m^2 + n^2}{2\sigma^2}}. \quad (19)$$

Fig. 18 Edge detection of an X-ray image of an aluminum wheel. The edges correspond to the boundaries of the image. The casting has two small defects (see arrows). The edges can be used to detect them

It should be noted that edges are detected when the magnitude of the gradient is maximal. It means that the location of edge pixels will not be modified if a mask $\mathbf{h}$ is replaced by $\lambda\mathbf{h}$ with $\lambda \neq 0$. Moreover, the direction of the gradient does not become modified either. For this reason, the elements of $\mathbf{h}$ are usually shown in their simplest way.

An example of estimation of gradient using the explained masks is illustrated in Fig. 19. After the gradient image is calculated, the edges are detected by thresholding. Thus, if the magnitude of the gradient is greater than a certain threshold, then the pixel of the output image is set as an edge pixel. The output for the mentioned example is illustrated in Fig. 20. We can see how the boundaries are detected, especially for those objects that are very dark in comparison with their background.

In Figs. 19 and 20, we show the edge detection of an X-ray image of an aluminum casting using the gradient operators according to the method explained in this section.

Laplacian of Gaussian

In “Gradient Estimation” section, we learned that the edges of a function can be located by detecting local maxima of the

magnitudes of gradients. We know that the location of the maximal values of the gradient coincides with zero crossing of the second derivative. In order to eliminate noisy zero crossings, which do not correspond to high gradient values, this method uses a Gaussian low-pass filter (see Fig. 21). The method, known as Laplacian of Gaussian (LoG), is based on a kernel and a zero-crossing algorithm.^[28] LoG kernel involves a Gaussian low-pass filter (10), which is suitable for the pre-smoothing of the noisy X-ray images. It is defined as the Laplacian of a 2D-Gaussian function:

$$h_{LoG}(m,n) = \frac{1}{2\pi\sigma^4} \cdot \left(2 - \frac{m^2 + n^2}{\sigma^2} \right) \cdot e^{-\frac{m^2 + n^2}{2\sigma^2}}. \quad (20)$$

LoG kernel is shown in Fig. 22. The parameter σ defines the width of the Gaussian function and, thus, the amount of smoothing and the edges detected (see Fig. 23). Using Eq. 8, we can calculate an image $\mathbf{Y}$ in which the edges of the original image are located by their zero crossing. After zero crossing, the detected edges $\mathbf{Z}$ correspond to the maximal (or minimal) values of the gradient image. In order to eliminate weak edges, a threshold θ is typically used. Thus, all edge pixels in $\mathbf{Z}$ that are not strong enough are ignored.

Fig. 19 Gradient of an X-ray of a pen case using different masks (Sobel, Prewitt, and Gaussian). See edge detection in Fig. 20

Fig. 20 Edge detection by thresholding a Gaussian gradient image of Fig. 19. The edges are detected for gradients greater than 3. In this representation, a logarithmical scale for the gray values was used

Fig. 21 Example of edge detection in 1D using LoG: the profile of the red line in an X-ray image is shown as $f(x)$. This function is filtered by a Gaussian low-pass filter obtaining $g(x)$. The gradient of $g(x)$, represented as $g'(x)$, shows the location of the maximal value (see dashed orange lines), which corresponds to the zero crossing of the second derivative of $g(x)$. The edges “1” and “2” are then detected

Fig. 22 LoG mask: (left) representation of Eq. 20; (right) profile for $n = 0$

Fig. 23 Example of LoG edge detection of a defect. Several values for σ and θ are presented. The smoothness of the edges is controlled by increasing σ . The reduction of noisy edges is controlled by increasing θ

The higher the threshold, the less edges will be detected. On the other hand, if $\theta = 0$, i.e., all zero-crossings are included, the edge image has closed and connected contours. As we will see in “Region Growing” section, this property is required when segmenting a region of the image.

In Fig. 23, we show the edge detection of the object of a part of a casting according to LoG algorithm explained in this section.

Canny Edge Detector

Canny proposes a 2D linear mask for edge detection based on an optimization approach,^[29] in which the following criteria are met:

- *Good detection:* The detection should respond to an edge (and not to noise).
- *Good localization:* The detected edge should be near the true edge.
- *Single response:* It should be one detected edge per true edge.

The optimal mask is similar to a derivative of Gaussian. Thus, the idea is to use this mask to find the local maxima of the gradient of the image. The practical implementation uses adaptive thresholding of the gradient (to detect strong and weak edges) with hysteresis (weak edges are detected only if they are connected to strong edges).

Segmentation

Image segmentation is defined as the process of subdividing an image into disjointed regions.^[5] A region is defined as a set of connected pixels that correspond to a certain *object of interest*. Obviously, these regions of interest depend on the application. For instance, in the inspection of aluminum castings with X-ray images, the idea of segmentation is to find regions with defects. Here, the

object of interest is the defects. An example is shown in Fig. 24, where the segmentation has the small spots that indicate defective areas.

Segmentation is one of the most difficult processes in image processing. Clearly, there are some simple applications in which certain segmentation techniques are very effective (e.g., separation between a casting and its background as shown in Fig. 28); however, in many other applications, segmentation is far from being solved as the appearance of the object of interest can become very intricate. This is the case of defect detection, where the segmentation of discontinuities can be extremely difficult due to problems of occlusion, noise, blur, and low contrast (see Fig. 25).

In image processing for fault detection, segmentation is used to detect (potential) regions that can be the objects of interest we are looking for. As mentioned in previous examples, segmentation divides the X-ray image into two areas: foreground and background. Foreground means the pixels of the object(s) of interest. Background means the remaining pixels of the image. Usually, a *binary image* is the output of the segmentation process as we can see in Figs. 24 and 28: where a pixel equals to “1” (white) is foreground, whereas “0” (black) means background. We use the term “potential” throughout to make it clear that a segmented region is not necessarily the final detected region. In many applications, the segmentation is just the first step of the whole detection process. In such cases, an additional step that analyzes the segmented region is required. This additional step can include multiple view analysis or a pattern recognition technique. The later extracts and classifies the features of the segmented region in order to verify whether it corresponds to the object that we are detecting or it is a *false detection*.

Thus, segmentation basically acts as a focus of attention that filters the information that is fed to the following steps; as such a failure in the segmentation is catastrophic for the final performance. In this section, we will review some basic

Fig. 24 Example of segmentation: detection of defects in an aluminum wheel (see details in Fig. 17)

Fig. 25 Problems when detecting a gun. Detection of defects (see arrows) can be a very complex task due to (a) occlusion, (b) noise, (c) blur, and (d) low contrast

segmentation techniques that have been used in X-ray testing: thresholding (“Thresholding” section), region growing (“Region Growing” section), and maximally stable extremal regions (“Maximally Stable Extremal Regions” section).

Thresholding

In some X-ray images, we can observe that the foreground is significantly darker than the background. This is the case of an X-ray image of a casting placed with holes as illustrated in Fig. 26. It is clear that the object of interest can be segmented using a very simple approach based on *thresholding*. In this section, we will explain a methodology based on an estimation of a global threshold using a statistical approach. This method was originally presented for color food images;^[30] however, it can be easily adapted for X-ray images.

The X-ray image to be segmented is stored in matrix **I**. In order to enhance the contrast of the image, a linear transformation can be performed (see “Contrast Enhancement” section). Additionally, a linear or nonlinear filter can be used for noise removal (see “Image Filtering” section). Here, after image enhancement and filtering, we obtain a new image **J** where $J_{\max} = 1$ and $J_{\min} = 0$. Image **J** has a bimodal histogram as shown in Fig. 26, where the left distribution corresponds to the casting and the right to the background. In this image, a first separation between the foreground and the background can be performed estimating a global threshold t . Thus, we define a binary image as

$$K(i, j) = \begin{cases} 1 & \text{if } J(i, j) < t \\ 0 & \text{else} \end{cases}, \quad (21)$$

Fig. 26 X-ray image of a wheel and its histogram

Fig. 27 Segmentation using threshold $t = 0.1, 0.2, \dots, 1.0$

where “1” means foreground and “0” background, which define two classes of pixels in the image. Figure 27 illustrates different outputs depending on t . The problem is to determine the “best” threshold t that separates the two modes of the histogram from each other. A good separation of the classes is obtained by ensuring (i) a small variation of the gray values in each class and (ii) a large variation of the gray values in the image.^[31] The first criterion is obtained by minimizing a weighted sum of the within-class variances (called *intraclass* variance $\sigma_w^2(t)$):

$$\sigma_w^2(t) = p_b(t)\sigma_b^2(t) + p_f(t)\sigma_f^2(t) \quad (22)$$

where the indices b and f denote, respectively, the background and foreground classes, and p and σ^2 are, respectively, the probability and the variance for the indicated class. These values can be computed from the histogram.

The second criterion is obtained by maximizing the between-class variance (called *interclass* variance $\sigma_B^2(t)$):

$$\sigma_B^2(t) = p_b(\mu_b(t) - \mu)^2 + p_f(\mu_f(t) - \mu)^2 \quad (23)$$

where μ_b , μ_f , and μ indicate the mean values of the background, the foreground, and the whole image, respectively.

The best threshold t can be estimated by a sequential search through all possible values of t that minimizes $\sigma_w^2(t)$ (or maximizes $\sigma_B^2(t)$). Both criteria, however, lead to the same result because the sum $\sigma_w^2 + \sigma_B^2$ is a constant and corresponds to the variance of the whole image.^[31] Thus, the threshold can be computed by minimizing the

intraclass variance $\sigma_w^2(t)$. In our example, the obtained threshold is $t = 0.5882$, which is approximately 0.6 (see Fig. 27).

In some cases, we can observe that the segmentation suffers from inaccuracy because there are many dark (bright) regions belonging to the foreground (background) that are below (above) the chosen threshold and therefore misclassified. For this reason, additional morphological processing such as (i) removing small objects and (ii) closing the binary image can be performed.

In the first step, we remove from binary image **K** obtained from Eq. 21 all connected regions that have fewer than n pixels. This operation is necessary to eliminate those isolated pixels of the background that have a gray value greater than the selected threshold. Empirically, we set $n = \frac{NM}{100}$, where NM is the number of pixels of the image.

The second step *closes* the image, i.e., the image is *dilated* and then *eroded*. The dilation is the process that incorporates into the foreground the background pixels that touch it. On the other hand, erosion is the process that eliminates all the boundary pixels of the foreground. The closing process (dilation followed by erosion) fills small holes and thins holes in the foreground, connecting nearby regions and smoothing the boundaries of the foreground without changing the area significantly.^[5] This operation is very useful in objects that have spots in the boundary. The result is shown in Fig. 28.

Fig. 28 Segmentation of a wheel using a global threshold

Fig. 29 Region growing: we start with a seed pixel that grows in each iteration in four directions until a boundary is found. The directions in this example are four: up, down, right, and left

Fig. 30 Region growing in an X-ray image using a seed pixel in the object of interest (a regular structure). The region is well segmented as we can see in the binary image and in boundaries

Region Growing

In region growing, we segment a region using an iterative approach. We start by choosing a seed pixel, as shown in Fig. 29. At this moment, our region is initialized and its size is one pixel only. We extract some features of the region, e.g., the gray value. We extract the same feature of each neighboring pixel. In our example, there are four neighbors (up, down, right, and left), as we can see in the third image of Fig. 29. We increase our region by adding similar neighboring pixels, i.e., those neighboring pixels that have a similar feature to the region. The whole process is continued, and each added pixel is a new seed for the next iteration, until no more neighboring pixels can be added.

In Fig. 29, we have a binary edge image. The feature that we use to establish the similarity is the value of the pixel. In our example, there are only two pixel values: “0” for the edge pixels and “1” for the remaining pixels. It means that the value of the pixel of the seed is 1, and in each iteration, we can add only those neighboring pixels, the value of which are 1. As we can see, the red region grows up from 1 pixel to 5, 12, 16, 22, and finally 24 pixels. The output is the red region of the last step.

Region growing can be used directly in X-ray images as illustrated in the example of Fig. 30. We start with a seed pixel, and neighboring pixels are added if they are similar enough. In this example, we show the performance of region growing in the segmentation of a part of a casting.

Fig. 31 X-ray image of an aluminum casting with a small defect at an edge (see defect pointed by green arrow). (First row) Original image. (Second row) LoG. (Third row) LoG and high gradient pixels. (First column) image representation. (Second column) 3D representation of red square. (Third column) Zoom of blue square. In this representation, the edge pixels are represented as red points superimposed onto the 3D surface. The output of this method is a binary image in which the real defects are closed by edges

The seed is chosen at pixel (100,60). The seed grows by adding neighboring pixels with similar gray values. In this example, the similarity between region and neighboring pixels is established if $|\bar{R} - r_n| \leq \theta$, where $\bar{R}$ is the average of the gray values of the region, r_n is the gray value of the neighboring pixel, and θ is the threshold. In this example, $\theta = 20$. The output of this example is the binary image shown in Fig. 30 at the right side.

Region growing can be used in X-ray testing in defect detection (see, e.g., interesting approaches in aluminum castings^[32] and welds^[33]). The method is illustrated in Fig. 32. The method uses an edge detection algorithm to obtain an edge image with closed and connected contours around the real defects. Thus, we use region growing to isolate each region enclosed by edges. The idea is to extract the features from this isolated region (e.g., area, average of gray value, contrast, etc.) that can be used in a classification strategy. In our example, a region is segmented using a very simple classifier (the features of a segmented region must be in certain ranges, e.g., $A_{\min} \leq \text{area} \leq A_{\max}$). Obviously, more sophisticated features and classifiers can be used to improve the segmentation performance in more complex scenarios as we will see in “X-ray Image Representation” and “Multiple View Analysis” sections.

In the example summarized in Fig. 33, we show how to segment defects in aluminum castings using binary images

of potential defects and some simple features that can be extracted from each potential region. In this example, we segment all those regions, the area of which is between 200 and 2000 pixels; the average of the gray value is <150 , and the contrast is >1.1 . The output of this example is shown in Fig. 32.

This method is very effective for regions of interest that have gray values significantly different from the background.

Nevertheless, the method may fail if the boundaries do not close a region of interest. This is the case in some defects of aluminum castings that are at an edge of a regular structure as illustrated in Fig. 31^c. In this problem, we can see that the edges of LoG algorithm (and other edge detection algorithms such as Sobel or Canny as well) cannot correctly find the defect’s edge. On the contrary, it finds the regular structure’s edge. To overcome this problem, we have to complete the remaining edges of these defects. A simple approach was suggested in the work of Mu et al.^[13] by thickening of the edges of the regular structure after LoG-edge detection: (i) the gradient of the original image is calculated. The gradient image is computed by taking

^cA video of this small defect can be watched at <http://youtu.be/e3wDJhq2Tqg>.

Fig. 32 Segmentation of defects in aluminum castings using region growing, edge detection, and some features. The size of the image in this example is 286×286 pixels

Fig. 33 Example of MSER: detection of a small defect at an edge of a regular structure of a casting

the square root of the sum of the squares of the gradient in horizontal and vertical directions (see Section “Gradient Estimation”). These are calculated by the convolution of the radioscopic image with the first derivative (in the corresponding direction) of the Gaussian low-pass filter used in the LoG filter. (ii) High gradient pixels are detected by thresholding. (iii) The resulting image is added to the LoG-edge detection image. Afterward, each closed region is segmented as a potential flaw. As the effectiveness of this method can be observed in Fig. 31, the defect on an edge of a regular structure could be satisfactorily closed. Thus, the method of Fig. 32 can be used.

Maximally Stable Extremal Regions

In order to understand the maximally stable extremal region (MSER) approach,^[34] the reader can imagine a simple video as follows: The video will have 256 frames. Frame t is defined as the binary image $\mathbf{I} < t$, where $\mathbf{I}$ is the input image to be segmented. If the binary image is black for “0” and white for “1,” at the beginning our video will be very dark and at the end very bright. In the middle, we will have some regions depending on the threshold^d. Thus, each region has an area $A(t)$ that depends on t . If the gray value of the region is very different from its background, the area of this region will be stable for some thresholds $t, t + 1, \dots, t + p$, i.e., $A(t) \approx A(t + 1) \dots \approx A(t + p)$. The key

idea of MSER is to segment those regions that fulfill the following:

$$\frac{\Delta A}{\Delta t} < \theta, \quad (24)$$

where θ is a threshold. It means that those regions whose sizes remain approximately stable by varying the segmentation threshold t are to be detected.

In the example of Fig. 32, we show the segmentation of an X-ray image of a small defect according to the MSER approach.

Image Restoration

Image restoration involves recovering detail in severely blurred images. This process is more efficient when the causes of the imperfections are known a priori.^[27] This knowledge may exist as an analytical model, or as a priori information in conjunction with knowledge (or assumptions) of the physical system that provided the imaging process in the first place. The purpose of restoration is then to estimate the best source image, given the blurred example and some a priori knowledge.

In this section, we concentrate on the particular case of blur caused by uniform linear motion, which may be introduced by relative motion between the detector and the object. Early work on restoring an image degraded by blurring calculated the de-blurring function as an inverse filtering. The inverse filtering evaluation of the blurring function h (or point spread function [PSF]) in the frequency domain tends

^dThe video can be found in <http://youtu.be/tWdJ-NFE6vY>.

to be very sensitive to noise.^[27] The cause of this sensitivity is the low-pass nature of the PSF: its frequency response $H(\omega)$ contains very small values, and small noise in the frequency regions where $1/H(\omega)$ is very large may be greatly emphasized. Sondhi^[27] proposed a non-iterative algorithm to find a solution to the uniform-blurring case, but the computational load is extremely high in small motions. Other two non-iterative approaches are presented in the work of Wright et al.^[25] In the first approach, the matrix left division calculates the restored signal as a signal that has the fewest possible nonzero components. This solution differs strongly from the original signal because the original signal must not have necessarily many zero components. The second approach, the Moore–Penrose pseudo-inverse of a matrix, finds a restored signal whose norm is smaller than any other solution. This solution is very good, but the estimation is based on singular-value decomposition (SVD), whose computation load is very high. In this section, we address the above problems and reduce the computational times significantly by using a new technique that minimizes the norm between the blurred and original images.

A blurred X-ray image $g(x, y)$ that has been degraded by a motion in the vertical direction x and the horizontal direction y can be modeled by

$$g(x, y) = \frac{1}{T} \int_0^T f(x - x_i(t), y - y_i(t)) dt, \quad (25)$$

where f , T , $x_i(t)$, and $y_i(t)$ represent, respectively, the deterministic original X-ray image, the duration of the exposure, and the time-varying components of motion in the x and y directions. In this case, the total exposure is obtained by integrating the instantaneous exposure over the time interval during which the shutter is open. By rotating the camera or by using a transformation that rotates the blurred image, a new system of coordinates is chosen in which $x_i(t)$ is zero. Considering that the original image $f(x, y)$ undergoes uniform linear motion in the horizontal direction y only, at a rate given by $y_i(t) = ct/T$, let us write Eq. 25, with $u = y - ct/T$, as

$$g(y) = \frac{1}{T} \int_0^T f(y - ct/T) dt = \frac{1}{c} \int_{y-c}^y f(u) du, \quad (26)$$

or as a digital that has been discretized in spatial coordinates by taking N samples $\Delta y = \frac{Y}{N}$ units apart:

$$g_k = \frac{1}{n} \sum_{i=0}^{n-1} f_{k+i}, \quad (27)$$

where

$$g_k = g\left(y_0 + (k-1)\frac{c}{n}\right),$$

$$f_k = f\left(y_0 + (k-1)\frac{c}{n} - c\right). \quad (28)$$

with $n = c/\Delta y$. Figure 34 shows a row $\mathbf{f} = [f_1 \dots f_M]^\top$ of an original image and its corresponding row $\mathbf{g} = [g_1 \dots g_N]^\top$ of the blurred image for $n = 3$ pixels. Equation 27 describes an underdetermined system of N simultaneous equations (one for each element of vector $\mathbf{g}$) and $M = N + n - 1$ unknowns (one for each element of vector $\mathbf{f}$) with $M > N$. This process is carried out for each row of the image. The degradation of $\mathbf{f}$ can be modeled using a convolution of f with h , where h is the PSF, a n -element vector defined as the impulse response of this linear system.^[27] Thus, element g_i of vector $\mathbf{g}$ is calculated as a weighted sum of n elements of $\mathbf{f}$, i.e., $g_i = h_1 f_i + h_2 f_{i+1} + \dots + h_n f_{i+n-1}$, for $i = 1 = N$. Using a circulant matrix, the convolution can be written as $\mathbf{H}\mathbf{f} = \mathbf{g}$:

$$\mathbf{g} = \mathbf{f} * \mathbf{h} = \begin{bmatrix} h_1 & \dots & h_n & 0 & 0 & 0 & 0 \\ 0 & h_1 & \dots & h_n & 0 & 0 & 0 \\ \vdots & & & \vdots & & & \\ 0 & 0 & \dots & 0 & h_1 & \dots & h_n \end{bmatrix} \begin{bmatrix} f_1 \\ f_2 \\ \vdots \\ f_M \end{bmatrix} = \begin{bmatrix} g_1 \\ g_2 \\ \vdots \\ g_N \end{bmatrix} \quad (29)$$

Fig. 34 Blurring process: (left) original row f ; (right) blurred row g

An example of a degradation process is shown in Fig. 35. In this example, we can see how the vertical lines of the casting cannot be recognized when the degradation is severe.

If the PSF is not exactly known, but if we know that it corresponds to a uniform linear motion, the parameter n can be estimated from the spectrum of the blurred image. An example is shown in Fig. 36. The 2D Fourier transformation of a blurred test is represented in Fig. 36a; in this case, a horizontal degradation took place with $n = 25$. The mean of its rows is illustrated in Fig. 36b. We can observe that the period of this function is inversely proportional to the length of the blurring process in pixels.

The problem of restoring an X-ray that has been blurred by uniform linear motion consists of solving the underdetermined system (Eq. 29). The objective is to estimate an original row per row ($\mathbf{f}$), given each row of a blurred ($\mathbf{g}$) and a priori knowledge of the degradation phenomenon ($\mathbf{H}$). Since there is an infinite number of exact solutions for $\mathbf{f}$ in the sense that $\mathbf{H}\mathbf{f} - \mathbf{g} = 0$, an additional criterion that finds a sharp restored image is required.

We observed that most solutions for $\mathbf{f}$ strongly oscillate. Figure 37 shows an example in which four different solutions for $\mathbf{f}$ are estimated; all solutions satisfy Eq. 29: $\mathbf{H}\mathbf{f} = \mathbf{g}$. Although these solutions are mathematically right, they do not correspond to the original signal. By the assumption that the components of the higher frequencies of $\mathbf{f}$ are not so significant in the wanted solution, these oscillations can be reduced by minimizing the distance between f_k and g_k , i.e., we take a vector as a sharp solution of $\mathbf{H}\mathbf{f} = \mathbf{g}$ so that

this presents the smallest distance between the original signal and the blurred signal. We seek then to minimize the objective function

$$J(\mathbf{f}, \mathbf{g}) = \sum_{k=1}^N (f_k - g_k)^2 \rightarrow \min. \quad (30)$$

The application of criteria of the minimization of the norm between the input and the output (MINIO) does not mean that $\mathbf{f}$ is equal to $\mathbf{g}$, because this solution does not satisfy the system of Eq. 29 and the sizes of $\mathbf{f}$ and $\mathbf{g}$ are different. The solution is also defined as the vector in the solution space of the underdetermined system $\mathbf{H}\mathbf{f} = \mathbf{g}$ whose first N components have the minimum distance to the measured data, i.e., where the first N elements are of $\mathbf{f}$. We can express vector $\hat{\mathbf{f}} = \mathbf{P}\mathbf{f}$, with $\mathbf{f}$ being an $N \times M$ matrix that projects the vector $\mathbf{f}$ on the support of $\mathbf{g}$:

$$\mathbf{P} = \begin{bmatrix} 1 & 0 & \dots & 0 & 0 & \dots & 0 \\ 0 & 1 & \dots & 0 & 0 & \dots & 0 \\ & & \ddots & & & \ddots & \\ 0 & 0 & \dots & 1 & 0 & \dots & 0 \end{bmatrix}. \quad (31)$$

The original optimization problem is now

$$\hat{\mathbf{f}} = \underset{\mathbf{f}}{\operatorname{argmin}} \|\mathbf{P}\mathbf{f} - \mathbf{g}\|^2 \quad (32)$$

subject to the constraint $\|\mathbf{P}\mathbf{f} - \mathbf{g}\|^2 = 0$. Applying the technique of *Lagrange multipliers*, this problem can be

Fig. 35 Degradation of an X-ray image of an aluminum wheel (768 × 572 pixels): original and degraded images with $n = 5, 15, 25, 25, 45$, and 60

Fig. 36 Spectrum of a blurred image which was degraded by uniform linear motion with $n = 25$ pixels. Left) 2D Fourier transformation of the original image of Fig. 35. Right) Mean of the rows of the Fourier transformation. The size of the degraded image is 768 × 548 pixels. It can be demonstrated that b is inversely proportional to n

alternatively formulated as an optimization problem without constraints:

$$V(\mathbf{f}) = \lambda \|\mathbf{H}\mathbf{f} - \mathbf{g}\|^2 + \|\mathbf{P}\mathbf{f} - \mathbf{g}\|^2 \rightarrow \min \quad (33)$$

if λ is large enough. The solution of this problem can be easily obtained by computing the partial derivative of criterion V with respect to the unknown $\mathbf{f}$:

$$\frac{\partial}{\partial \mathbf{f}} V(\mathbf{f}) = 2\lambda \mathbf{H}^* (\mathbf{H}\mathbf{f} - \mathbf{g}) + 2\mathbf{P}^* (\mathbf{P}\mathbf{f} - \mathbf{g}) = 0, \quad (34)$$

then is

$$\hat{\mathbf{f}} = [\lambda \mathbf{H}^T \mathbf{H} + \mathbf{P}^T \mathbf{P}]^{-1} [\lambda \mathbf{H} + \mathbf{P}] \mathbf{g}. \quad (35)$$

This solution for the example of Fig. 37b is almost identical to the original sharp input signal of Fig. 37a. Figure 38 shows three different restoration examples.

In the example of Fig. 38, we simulate an X-ray image that has been degraded by a horizontal motion. The image is restored using MINIO algorithm (Eq. 35). Details of the baggage are not discernible in the degraded image, but are recovered in the restored image.

The restoration quality is equally as good as the classical methods (see, e.g., the work of Zahn and Roskies^[27]), whereas the computation load is decreased considerably (see comparisons in the work of Mery and Pedreschi^[35]).

X-RAY IMAGE REPRESENTATION

As we learned in the previous section, in image processing for X-ray testing, segmentation is used to detect (potential)

Fig. 37 Restoration of row $\mathbf{f}$: (a) original row; (b) degraded row with $n = 2$; (c, d, e, and f) four possible solutions that satisfy $\mathbf{H}\hat{\mathbf{f}} = \mathbf{g}$

Fig. 38 Restoration in simulated degraded X-ray images. Each column shows the original, degraded with n pixels, and restored images. The size of the images are, respectively, 574×768 , with $n = 30$; 574×768 , with $n = 40$; and 768×574 , with $n = 60$

regions that can be the objects of interest that we are looking for (see “Segmentation” section). As segmented potential regions frequently set off false detections, an analysis of the segmented regions can significantly improve the effectiveness of detection. Measuring certain characteristics of the segmented regions (*feature extraction*) can help us to distinguish the false detection, although some of the features extracted are either irrelevant or not correlated. Therefore, a feature selection must be performed. Depending on the values returned for the selected features, we can try to classify each segmented potential region in one of the following two classes: *background* or *object of interest*.

In this section, we will explain several features that are normally used in image analysis and computer vision for X-ray testing. In our description, features will be divided into two groups: *geometric* and *intensity*. Furthermore, we will cover some local descriptors and sparse representations that can be used in many X-ray testing applications. In this section, we shall concentrate on the extraction and selection of features, whereas in the following section, we will discuss the classification problem itself.

We will use Fig. 39 as our example in the description of features. In our example, we use an X-ray image of a circular defect. The segmentation is a binary image that gives information about the pixels that belongs to our object of interest (the defect). Geometric features are extracted from this binary image. Moreover, intensity features are extracted from the intensity image considering the pixels of the segmentation. Some intensity features consider only the gray values inside the segmented region, whereas other ones take into account both gray values inside and outside the region (e.g., contrast).

Geometric Features

These provide information on the location, size, and shape of the segmented region. Location and size features, such as center of mass, perimeter, height, and width, are given

in pixels. Shape features are usually coefficients without units. It is worth mentioning that we distinguish three different zones in the segmented image (see Fig. 39b): the segmented region (white zone $\mathfrak{R}$), the boundary (red edge pixels ℓ), and the background (black zone).

Basic Geometric Features

In this section, we will summarize the basic geometric features that can be easily extracted.

Height and Width The height and width of a region can be defined as

$$\begin{aligned} h &= i_{\max} - i_{\min} + 1 \\ w &= j_{\max} - j_{\min} + 1 \end{aligned} \quad (36)$$

where $i_{\max}$ and $i_{\min}$ are the maximal and minimal values that take coordinate i in the region. The same is valid for $j_{\max}$ and $j_{\min}$ in the j direction.

Area and Perimeter We define the area A of a region as the number of pixels that belong to the region. On the other hand, the perimeter L is the number of pixels that belong to the boundary. In the region of Figure 39, the area and the perimeter are the number of the white and the number of the red pixels, respectively. More accurate measurements for area and perimeter can also be estimated:^[36] for instance, the boundary of the region can be fitted to a curve with known area and length; however, the computational time of such approaches can be extremely long if there are thousands of regions to be measured. Moreover, the shape of the region can be much more complex than the shape of a simple circle as shown in Fig. 33. We should remember, therefore, that the goal of feature extraction is not the accurate measurement; rather, it is simply the extraction of features that can be used in a classification approach to separate our classes (objects of interest from the background).

Fig. 39 Example of a region: (a) X-ray image; (b) segmented region (white pixels); (c) 3D representation of the gray values

Center of Mass This provides information about the location of the region. It is computed as the average of coordinates i and j in pixels that belong to region $\mathcal{R}$:

$$\bar{i} = \frac{1}{A} \sum_{i \in \mathcal{R}} i \quad \bar{j} = \frac{1}{A} \sum_{j \in \mathcal{R}} j \quad (37)$$

where A is the area of the region, i.e., the number of pixels of the region.

Roundness Shape features are usually the attributed coefficients without units. An example is roundness that is defined as

$$R = \frac{4 \cdot A \cdot \pi}{L^2} \quad (38)$$

The roundness R is a value between 1 and 0. $R = 1$ means a circle, and $R = 0$ corresponds to a region without an area.

Other Basic Features There are some useful features that can be extracted as follows:^[25]

- *Euler number*: The number of objects in the region minus the number of holes in those objects.
- *Equivalent diameter*: The diameter of a circle with the same area as the region.
- *Major axis length and minor axis length*: The length (in pixels) of the major and minor axes of the ellipse that have the same normalized second central moments as the region.
- *Orientation*: The angle (in degrees ranging from -90° to 90°) between the x -axis and the major axis of the ellipse that has the same second moments as the region.
- *Solidity*: The proportion of the pixels in the convex hull that are also in the region.
- *Extent*: The ratio of pixels in the region to pixels in the total bounding box.
- *Eccentricity*: The eccentricity of the ellipse that has the same second moments as the region.

Elliptical Features

Elliptical features can be used to extract the information about location, size, and shape of a region. They are extracted from a fitted ellipse to the boundary of the region.^[37] From this ellipse, we can extract the center, the length of the axes, the orientation, and the eccentricity.

The pixels of the boundary are defined as (x_i, y_i) for $i = 1 \dots L$. It is well known that an ellipse is defined as

$$ax^2 + bxy + cy^2 + dx + ey + f = 0, \quad (39)$$

which can be written as $\mathbf{a}^T \mathbf{x} = 0$, where $\mathbf{a} = [a \ b \ c \ d \ e \ f]^T$ is a vector that includes the parameters of the ellipse and $\mathbf{x} = [x^2 \ xy \ y^2 \ x \ y \ 1]^T$ is a vector that includes the coordinates of a point (x, y) that lies on the ellipse.

If our region is elliptical, then for each point (x_i, y_i) , we have $\mathbf{a}^T \mathbf{x}_i = 0$ with $\mathbf{x}_i = [x_i^2 \ x_i y_i \ y_i^2 \ x_i \ y_i \ 1]^T$. Nevertheless, in practice, the regions are not perfectly elliptical, not only because real regions have different shapes, but also because there is a discretization error when forming a digital image. For this reason, we look for a vector $\mathbf{a}$ so that $\mathbf{a}^T \mathbf{x}_i \rightarrow \min$ for every point $i = 1 \dots L$. That is, we can formulate the estimation of the parameters of the ellipse as an optimization problem as follows:

$$\|\mathbf{X}\mathbf{a}\| \rightarrow \min \quad (40)$$

where $\mathbf{X}$ is the matrix with L rows whose i th row is $\mathbf{x}_i^T$. Usually, a solution can be found by minimizing Eq. 40 subject to $\|\mathbf{a}\| = 1$. In this case, $\mathbf{a}$ is the last column of matrix $\mathbf{V}$, where $\mathbf{X} = \mathbf{U}\mathbf{S}\mathbf{V}^T$ is the SVD of $\mathbf{X}$.^[38]

The elliptical features can be extracted by writing Eq. 39 as follows:

$$\left(\frac{x - x_0}{a_e} \right)^2 + \left(\frac{y - y_0}{b_e} \right)^2 = 1 \quad (41)$$

where

$$a_e = \frac{1}{\sqrt{s} a_p}, b_e = \frac{1}{\sqrt{s} b_p} \quad (42)$$

with

$$s = \frac{1}{v - f} \quad v = \mathbf{t}^T \mathbf{T} \mathbf{t}$$

$$\mathbf{T} = \begin{bmatrix} a & b/2 \\ b/2 & c \end{bmatrix}$$

$$\mathbf{t} = \begin{bmatrix} x_0 \\ y_0 \end{bmatrix} = \frac{1}{2} \mathbf{T}^{-1} \begin{bmatrix} d \\ e \end{bmatrix}$$

$$\begin{aligned} a_p &= a \cos^2(\alpha) + b \cos(\alpha) + c \sin^2(\alpha) \\ b_p &= a \sin^2(\alpha) - b \cos(\alpha) + c \cos^2(\alpha) \end{aligned}$$

and

$$\alpha = \frac{1}{2} \arctan\left(\frac{b}{a - c}\right) \quad (43)$$

The axes of the ellipse are defined by a_e and b_e , the center of the ellipse is located on (x_0, y_0) , and the orientation is α . Thus, the eccentricity is defined by

$$e_x = \frac{\min(a_e, b_e)}{\max(a_e, b_e)} \quad (44)$$

For circular shapes, the eccentricity as the roundness (Eq. 38) takes values between 0 and 1, where 1 means a perfect circle.

Fourier Descriptors

Shape information—invariant to scale, orientation, and position—can be measured using *Fourier descriptors*.^[39–41] The coordinates of the pixels of the boundary are arranged as a complex number $i_k + j \cdot j_k$, with $j = \sqrt{-1}$ and $k = 0, \dots, L - 1$, where L is the perimeter of the region, and pixels k and $k + 1$ are connected. The complex boundary function can be considered as a periodical signal of period L . The discrete Fourier transform^[5] gives a characterization of the shape of the region. The Fourier coefficients are defined by

$$F_n = \sum_{k=0}^{L-1} (i_k + j \cdot j_k) e^{-j \frac{2\pi kn}{L}} \text{ for } n = 0, \dots, L - 1. \quad (45)$$

The Fourier descriptors correspond to the coefficients F_n for $n > 0$. The Fourier coefficient F_0 is not used because it gives information about the location of the region. The magnitude and phase of Fourier descriptors give information about orientation and symmetry of the region. In general, only the magnitude $|F_n|$ is used. Fourier descriptors are invariant under rotation (Fig. 40).

Invariant Moments

The statistical moments are defined by

$$m_{rs} = \sum_{i,j \in \mathfrak{R}} i^r j^s \quad \text{for } r, s \in \mathbb{N}, \quad (46)$$

where $\mathfrak{R}$ is the set of pixels that belong to the region (see white pixels in Fig. 39b). The parameter $r + s$ corresponds to the order of the moment. The reader can demonstrate that the zeroth moment m_{00} is equal to the area A of the region. Moreover, the center of mass of the region is easily defined by

$$\bar{i} = \frac{m_{10}}{m_{00}} \quad \bar{j} = \frac{m_{01}}{m_{00}} \quad (47)$$

The center of mass and statistical moments of higher order, however, are not invariant to the location of the region. This can be useful for detecting objects that must be in certain locations. Nevertheless, when objects of interest may be everywhere in the image we must use features that are invariant to the position. Using the center of mass, the central moments are defined. They are invariant to the position:

$$\mu_{rs} = \sum_{i,j \in \mathfrak{R}} (i - \bar{i})^r (j - \bar{j})^s \quad \text{for } r, s \in \mathbb{N}. \quad (48)$$

Other known moments that can be used are the well-known Hu moments.^[42,43] These were developed using the central moments as follows:

$$\begin{aligned} \phi_1 &= \eta_{20} + \eta_{02} \\ \phi_2 &= (\eta_{20} - \eta_{02})^2 + 4\eta_{11}^2 \\ \phi_3 &= (\eta_{30} - 3\eta_{12})^2 + (3\eta_{21} - \eta_{03})^2 \\ \phi_4 &= (\eta_{30} + \eta_{12})^2 + (\eta_{21} + \eta_{03})^2 \\ \phi_5 &= (\eta_{30} - 3\eta_{12})(\eta_{30} + \eta_{12}) \left[(\eta_{30} + \eta_{12})^2 - 3(\eta_{21} + \eta_{03})^2 \right] \\ &\quad + (3\eta_{21} - \eta_{03})(\eta_{21} + \eta_{03}) \left[3(\eta_{30} + \eta_{12})^2 - (\eta_{21} + \eta_{03})^2 \right] \\ \phi_6 &= (\eta_{20} - \eta_{02}) \left[(\eta_{30} + \eta_{12})^2 - (\eta_{21} + \eta_{03})^2 \right] \\ &\quad + 4\eta_{11}(\eta_{30} + \eta_{12})(\eta_{21} + \eta_{03}) \\ \phi_7 &= (3\eta_{21} - \eta_{03})(\eta_{30} + \eta_{12}) \left[(\eta_{30} + \eta_{12})^2 - 3(\eta_{21} + \eta_{03})^2 \right] \\ &\quad - (\eta_{30} - 3\eta_{12})(\eta_{21} + \eta_{03}) \left[3(\eta_{30} + \eta_{12})^2 - (\eta_{21} + \eta_{03})^2 \right] \end{aligned} \quad (49)$$

with

Fig. 40 Elliptical features of two defects (the original image, the boundaries of the segmentation, and the estimated ellipse are shown). The size of the image is 256×256 pixels. In this example, the coordinates of the center of each ellipse correspond to the yellow cross. The estimated length of each axis are 9.6 and 12.1 pixels for the small ellipse and 32.7 and 39.7 for the large ellipse. The orientations (with respect to vertical axis in a counterclockwise direction) are 59.6° and -74.6° , respectively

$$\eta_{rs} = \frac{\mu_{rs}}{\mu_{00}^2} \quad t = \frac{r+s}{2} + 1.$$

Hu moments are invariant to translation, rotation, and scale. It means that regions that have the same shape, but have a different size, location, and orientation, will have similar Hu moments.

In addition, there are similar invariant features, called Gupta moments, that are derived from the pixels of the boundary (instead of the region).^[44] They are invariant to translation, rotation, and scale.

Sometimes, it is necessary to have features that are invariant to affine transformation. For this reason, Flusser moments, i.e., features invariant to translation, rotation, scale, and affine transformation, were derived from the second- and third-order central moments:^[45,46]

$$\begin{aligned} I_1 &= \frac{\mu_{20}\mu_{02} - \mu_{11}^2}{\mu_{00}^4} \\ I_2 &= \frac{\mu_{30}^2\mu_{03}^2 - 6\mu_{30}\mu_{12}\mu_{03} + 4\mu_{30}\mu_{12}^3 + 4\mu_{21}^3\mu_{03} - 3\mu_{21}^2\mu_{21}^2}{\mu_{00}^{10}} \\ I_3 &= \frac{\mu_{20}(\mu_{21}\mu_{03} - \mu_{12}^2) - \mu_{11}(\mu_{30}\mu_{03} - \mu_{21}\mu_{12}) + \mu_{02}(\mu_{30}\mu_{12} - \mu_{21}^2)}{\mu_{00}^7} \\ I_4 &= \frac{(\mu_{20}^3\mu_{03}^2 - 6\mu_{20}^2\mu_{11}\mu_{12}\mu_{03} - 6\mu_{20}^2\mu_{02}\mu_{21}\mu_{03} + 9\mu_{20}^2\mu_{02}\mu_{12}^2 \\ &\quad + 12\mu_{20}\mu_{11}^2\mu_{21}\mu_{03} + 6\mu_{20}\mu_{11}\mu_{02}\mu_{30}\mu_{03} - 18\mu_{20}\mu_{11}\mu_{02}\mu_{21}\mu_{12} \\ &\quad - 8\mu_{11}^3\mu_{30}\mu_{03} - 6\mu_{20}\mu_{02}^2\mu_{30}\mu_{12} + 9\mu_{20}\mu_{02}^2\mu_{21} + 12\mu_{11}^2\mu_{02}\mu_{30}\mu_{12} \\ &\quad - 6\mu_{11}\mu_{02}^2\mu_{30}\mu_{21} + \mu_{02}^3\mu_{30}^2}{\mu_{00}^{11}} \end{aligned} \quad (50)$$

Intensity Features

These provide information about the intensity of a region. For gray value images, e.g., X-ray images, there is only one intensity channel. The basic intensity features are computed using the gray values in the image, where $x(i, j)$ denotes the gray value of pixel.

Basic Intensity Features

In this section, we summarize the basic intensity features that can be easily extracted.

Mean Gray Value The mean gray value of the region is computed as

$$G = \frac{1}{A} \sum_{i,j \in \mathfrak{R}} x(i, j) \quad (51)$$

where $\mathfrak{R}$ is the set of pixels of the region and A is the area. A 3D representation of the gray values of the region and its

neighborhood of our example is shown in Fig. 39. In this example, $G = 142.70$ ($G = 0$ means 100% black and $G = 255$ corresponds to 100% white).

Mean Gradient in the Boundary This feature gives information about the change of the gray values in the boundary of the region. It is computed as

$$C = \frac{1}{L} \sum_{i,j \in \mathfrak{R}} x'(i, j) \quad (52)$$

where $x'(i, j)$ means the gradient of the gray value function in pixel (i, j) (see “Gradient Estimation” section) and ℓ is the set of pixels that belong to the boundary of the region. The number of pixels of this set corresponds to L , the perimeter of the region.

Mean Second Derivative This feature is computed as

$$D = \frac{1}{A} \sum_{i,j \in \mathfrak{R}} x''(i, j) \quad (53)$$

where $x''(i, j)$ denotes the second derivative of the gray value function in pixel (i, j) . The LoG operator can be used to calculate the second derivative of the image. If $D > 0$, we have a region that is darker than its neighborhood as shown in Fig. 21.

Contrast

The contrast gives a measure of the difference in the gray value between region and its neighborhood. The smaller the gray value difference, the smaller the contrast. In this work, region and neighborhood define a zone. The zone is considered as a window of the image:

$$g(i, j) = x(i + i_r, j + j_r) \quad (54)$$

for $i = 1, \dots, 2h + 1$ and $j = 1, \dots, 2w + 1$, where h and w are the height and width, respectively, as expressed in Eq. 36. The off-sets i_r and j_r are defined as $i_r = \bar{i} - h - 1$, $j_r = \bar{j} - b - 1$, where (i, j) denotes the center of mass of the region as computed in Eq. 47.

Contrast is a very important feature in fault detection, as the differences in the gray values are good for distinguishing a region from its neighborhood. The smaller the gray value difference, the smaller the contrast. In order to visualize the contrast, we can use a 3D representation with three coordinates (x, y, z) , where (x, y) are used to represent the location of a pixel (i, j) and z is used for the representation of the gray value. An example is illustrated in Fig. 39c that shows the 3D representation of Fig. 39a. The reader can observe in this example a high contrast region.

There are many definitions of contrast. A common definition of contrast is given using texture features (see, e.g., Section “Statistical Textures—Haralick”). Other simple

definitions of contrast are given in the work of Rumelhart et al.^[46] and Carrasco and Mery.^[47]

$$\begin{aligned} K_1 &= \frac{G - G_e}{G_3}, \\ K_2 &= \frac{G - G_e}{G + G_e}, \\ K &= \ln(G/G_e). \end{aligned} \quad (55)$$

where G and G_e denote the mean gray values in the region and the neighborhood, respectively.

Two further definitions of contrast are given in the work of Faugeras^[48] where new contrast features are suggested. According to Fig. 41, these new features can be calculated in four steps: (i) we take a profile in the i direction and in the j direction centered in the mass center of the region (see P_1 and P_2 , respectively); (ii) we calculate the ramps R_1 and R_2 that are estimated as a first-order function that contains the first and last points of P_1 and P_2 ; (iii) new profiles without background are computed as $Q_1 = P_1 - R_1$ and $Q_2 = P_2 - R_2$ (they are stored together as $Q = [Q_1 \ Q_2]$); and (iv) the new contrast features are given by

$$K_\sigma = \sigma_Q \quad \text{and} \quad K = \ln(Q_{\max} - Q_{\min}). \quad (56)$$

Another definition of contrast can be found in the work of Bengio et al.,^[49] where the contrast is given by the mean of absolute differences between the pixel values and the mean of adjacent (e.g., eight adjacent pixels):

$$K_c = \frac{1}{A_T} \sum_{(i,j) \in T} |g(i,j) - \mu_{A(i,j)}|, \quad (57)$$

where A_T is the area of the region and its neighborhood, and $\mu_{A(i,j)}$ is the mean value of pixel locations adjacent to pixel (i,j) .

Other Basic Features A simple texture feature is the local variance.^[50] This is given by

$$\sigma_s^2 = \frac{1}{4hb + 2h + 2b} \sum_{i=1}^{2h+1} \sum_{j=1}^{2b+1} (g(i,j) - \bar{g})^2, \quad (58)$$

where $\bar{g}$ denotes the mean gray value in the zone.

Other basic intensity features such as kurtosis and skewness can be computed as Eq. 58.

Crossing Line Profiles

An approach based on *crossing line profiles* (CLPs) was originally developed to detect aluminum casting defects,^[32] however, it can be used to detect spots in general or regions that have some gray value differences with their neighborhood. As the contrast between a defect and a defect-free neighborhood is distinctive, the detection is usually performed by thresholding this feature (as we have already learned in “Contrast” section). Nevertheless, this measurement suffers from accuracy error when the neighborhood is not homogeneous, e.g., when a defect is at an edge of a regular structure of the test object (see Fig. 31). For this reason, many approaches use a priori information about the location of regular structures of the test piece. CLP is able to detect those defects without a priori knowledge using CLPs, i.e., the gray-level profiles along straight lines crossing each segmented potential region in the middle. The profile that contains the most similar gray levels in the extremes is selected. Hence, the homogeneity of the neighborhood is ensured. Features from the selected profile are extracted.

In this approach, we follow a simple automated segmentation approach based on Figs. 31 and 33. The steps of detection based on CLP are shown in Fig. 42. First, a LoG kernel and a zero-crossing algorithm are used to detect the edges of the X-ray images. The LoG operator involves a Gaussian low-pass filter, which is a good choice for the pre-smoothing of our noisy images that are obtained without frame averaging. The resulting binary edge image should produce at real defects closed and connected contours that demarcate *regions*. However, a region of interest may not be perfectly enclosed if it is located at an edge of a regular structure as shown in Fig. 42c. In order to complete the remaining edges of these defects, a thickening of the edges of the regular structure is performed as follows: (i) the gradient of the original image is calculated (see Fig. 42d); (ii) by thresholding the gradient image at a high gray level, a new binary image is obtained; and (iii) the resulting image is added to the zero-crossing

Fig. 41 Computation of Q for contrast features for region of Fig. 39: (a) profile in the i direction; (b) profile in the j direction; (c) fusion of profiles: $Q = [Q_1 \ Q_2]$

Fig. 42 Detection of flaws: (a) radioscopic image with a small flaw at an edge of a regular structure; (b) Laplacian-filtered image with $\sigma = 1.25$ pixels (kernel size = 11×11); (c) zero-crossing image; (d) gradient image; (e) edge detection after adding high gradient pixels; (f) detected flaw using feature F_1 extracted from a CLP

image (see Fig. 42e). Afterward, each closed region is segmented as a potential flaw. For details, see a description of the method in the work of Mu et al.^[13]

This is a very simple detector of potential regions with a large number of false detections flagged erroneously. However, the advantages are as follows: (i) it is a single detector (it is the same detector for each image); (ii) it is able to identify potential defects independent of the placement and the structure of the specimen, i.e., without a priori information of the design structure of the test piece; and (iii) the detection rate of real flaws is very high ($\sim 90\%$). In order to reduce the number of the false positives, the segmented regions must be measured and classified.

A segmented potential region is defined as a region enclosed by edges of the binary image obtained in the edge detection (see connected black pixels in Fig. 42e). For each segmented region, a window g is defined from the X-ray image x as $g(i, j) = x(i + i_r, j + j_r)$ for $i = 1 \dots 2h + 1$ and $j = 1 \dots 2w + 1$, where h and w are the height and width, respectively, of the region as defined in Eq. 36. The offsets i_r and j_r are defined as $i_r = i - h - 1$ and $j_r = j - w - 1$, where (i, j) denotes the coordinates of the center of mass of the region (Eq. 47), rounded to the nearest integers. Hence, g is a window of size $(2h + 1) \times (2w + 1)$, in which the middle pixel corresponds to the center of mass of the segmented potential flaw, i.e., $g(h + 1, w + 1) = x(\bar{i}, \bar{j})$.

Now, we define the CLP P_θ as the gray-level function along a straight line of window g through the middle pixel $(h + 1, w + 1)$ forming an angle θ with the i -axis. In “Contrast” section, P_0 and $P_{\pi/2}$ were analyzed together in order to obtain two features, K and K_σ , that give a measurement of the difference between the maximum and the minimum,

and the standard deviation of both CLPs. However, the analysis does not take into account that the profiles could include a nonhomogeneous area. For example, if a non-defect region is segmented at an edge of a regular structure, it could be that P_0 (or $P_{\pi/2}$) includes a significant gray-level change of the regular structure. In this case, the variation of the profile will be large, and therefore, the region will be erroneously classified as defect.

In order to avoid this problem, we suggest an individual analysis of eight CLPs P_θ , at $\theta = \frac{k\pi}{8}$, for $k = 0, \dots, 7$, as illustrated in Fig. 43. In this analysis, the CLP that contains the most similar gray levels in the extremes is selected. Hence, the attempt is made to ensure the homogeneity of the neighborhood filtering out those profiles that present a high gray-level change in the edge of the regular structure. In the example of Fig. 43, the selected profile is obtained for $k = 5$ where the gray values of the extremes are both approximately equal to 150. We can observe that the selected crossing line is approximately perpendicular to the direction of the gradient of the X-ray image without defect. This coincides with one of the criteria used by approaches with a priori knowledge: the selected pixels of the defect-free area are located perpendicular to the direction of the gradient of the piece’s contour.^[51]

Before the features are extracted, a preprocessing of the selected CLP is performed as follows: (i) the selected profile is resized to size $n = 32$ using a nearest neighbor interpolation. The resized profile will be denoted by P . (ii) In order to obtain a defect profile without the background of the regular structure, P is linearly transformed by $Q_i = mP_i + b$, for $i = 1, \dots, n$, where m and b are so chosen that $Q_1 = Q_n = 0$.

Fig. 43 CLPs for the window shown in Fig. 42a

Finally, the proposed features are extracted from the normalized profile Q . They are defined as follows:

$$\begin{aligned}\bar{Q} &= \text{mean}(Q) \\ \sigma_Q &= \text{std}(Q) \\ \Delta_Q &= \max(Q) - \min(Q) \\ F_i &= \sum_{k=0}^{n-1} Q_{k+1} e^{-j \frac{2\pi k i}{n}} \text{ for } i = 1, \dots, 4.\end{aligned}\quad (59)$$

where $\bar{Q}$ is the mean of Q , σ_Q is the standard deviation of Q , Δ_Q is the difference between the maximum and the minimum of Q , and F_i is the magnitude of the i th harmonic of the discrete Fourier transform of Q for $i = 1 \dots 4$.

In the example of Fig. 42, we show how to detect a very small casting defect that is located at the edge of a regular structure using area and CLP features. We follow the general block diagram of Fig. 33, where area and contrast features are extracted for each region defined by enclosed edges. The detection is performed if the size of the region is between some thresholds and a CLP feature is high enough. The output of this example is shown in Figs. 42 and 43.

CLP features were tested on detecting casting defects. In this experiment, 50 X-ray images of aluminum wheels were analyzed. In the segmentation, approximately

23,000 potential flaws were obtained, in which there were 60 real defects. Some of these were existing blow holes. The other defects were produced by drilling small holes in positions of the casting that were known to be difficult to detect. In the performance analysis, the best result was achieved by our feature F_1 (Eq. 59). The class distribution between class “defect” and “non-defect” (or regular structure) is illustrated in Fig. 44. The reader can observe the effectiveness of the separation clearly. For more details, see the work of Mery.^[32]

Fig. 44 Class distribution of CLP feature F_1 in detection of casting defects

Texture Representation

These features provide information about the distribution of the gray values in the image. In this work, however, we restrict the computation of the texture features for a zone only defined as region and neighborhood (see Eq. 54).

Statistical Textures—Haralick

Statistical texture features can be computed using the co-occurrence matrix $\mathbf{P}_{kl}$.^[52] The element $P_{kl}(i, j)$ of this matrix for a zone is the number of times, divided by N_T , that gray levels i and j occur in two pixels separated by that distance and direction given by the vector (k, l) , where N_T is the number of pixel pairs contributing to build matrix $\mathbf{P}_{kl}$. In order to decrease the size $N_x \times N_x$ of the co-occurrence matrix, the grayscale is often reduced to eight gray levels. From the co-occurrence matrix, several texture features can be computed. Haralickin^[52] proposes (here $p(i, j) = P_{kl}(i, j)$):

Angular second moment	$f_1 = \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} [p(i, j)]^2$
Contrast	$f_2 = \sum_{n=0}^{N_x-1} n^2 \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} p(i, j) \text{ for } i - j = n$
Correlation	$f_3 = \frac{1}{\sigma_x \sigma_y} \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} [ij \cdot p(i, j) - \mu_x \mu_y]$
Sum of squares	$f_4 = \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} (i - j)^2 p(i, j)$
Inverse difference moment	$f_5 = \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} \frac{p(i, j)}{1 + (i - j)^2}$
Sum average	$f_6 = \sum_{i=2}^{2N_x} i \cdot p_{x+y}(i)$
Sum variance	$f_7 = \sum_{i=2}^{2N_x} (i - f_6)^2 \cdot p_{x+y}(i) \quad (60)$
Sum entropy	$f_8 = - \sum_{i=2}^{2N_x} p_{x+y}(i) \cdot \log(p_{x+y}(i))$
Entropy	$f_9 = - \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} p(i, j) \log(p(i, j))$
Difference variance	$f_{10} = \text{var}(p_{x-y})$
Difference entropy	$f_{11} = - \sum_{i=0}^{N_x-1} p_{x-y}(i) \cdot \log(p_{x-y}(i))$
Information measures of correlation 1	$f_{12} = \frac{f_9 - HXY1}{\max(HX, HY)}$
Information measures of correlation 2	$f_{13} = \sqrt{1 - \exp(-2(HXY2 - HXY))}$
Maximal correction coefficient	$f_{14} = \sqrt{\lambda_2}$

where μ_x, μ_y, σ_x , and σ_y are the means and standard deviations of p_x and p_y , respectively, with

$$\begin{aligned}
 p_x &= \sum_{j=1}^{N_x} p(i, j) \\
 p_y &= \sum_{i=1}^{N_x} p(i, j) \\
 p_{x+y}(k) &= \sum_{i=1}^{N_x} \sum_{j=1+i-j=k}^{N_x} p(i, j) \text{ for } k = 2, 3, \dots, 2N_x \\
 p_{x-y}(k) &= \sum_{i=1}^{N_x} \sum_{j=1|i-j=k}^{N_x} p(i, j) \text{ for } k = 0, 1, \dots, N_x - 1
 \end{aligned}$$

and

$$\begin{aligned}
 HX &= - \sum_{i=1}^{N_x} p_x(i) \log(p_x(i)) \\
 HY &= - \sum_{j=1}^{N_x} p_y(j) \log(p_y(j)) \\
 HXY1 &= - \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} p(i, j) \log(p_x(i) p_y(j)) \\
 HXY2 &= - \sum_{i=1}^{N_x} \sum_{j=1}^{N_x} p_x(i) p_y(j) \log(p_x(i) p_y(j))
 \end{aligned}$$

In f_{14} , λ_2 is the second largest eigenvalue of Q defined by

$$Q(i, j) = \sum_{k=1}^{N_x} \frac{p(i, k) p(j, k)}{p_x(i) p_y(k)}$$

The texture features are extracted for four directions (0° – 180° , 45° – 225° , 90° – 270° , and 135° – 315°) in different distances $d = \max(k, l)$. That is, for a given distance d , we have four possible co-occurrence matrices: P_{0d} , P_{45d} , P_{90d} , and P_{135d} . For example, for $d = 1$, we have $(k, l) = (0, 1), (1, 1), (1, 0)$, and $(-1, 1)$. After Haralick, 14 texture features using each co-occurrence matrix are computed (Eq. 60), and the mean and range for each feature are calculated, i.e., we obtain $14 \times 2 = 28$ texture features for each distance d . The features will be denoted as $\bar{f}_i$ for the mean and f_i^Δ for the range, for $i = 1 \dots 14$.

Local Binary Patterns

Local binary pattern (LBP) was proposed as a texture feature.^[53] The idea is to extract the texture information from occurrence histogram of LBPs computed from the relationship between each pixel intensity value and its eight neighbors. The LBP features are the frequencies of each one of the histogram bins. LBP is computed in three steps: (i) coding, (ii) mapping, and (iii) histogram.

Coding Each pixel (i, j) of the input image has a set of neighbors. Typically, the set of eight neighbors defined by the eight connected pixels is used. However, more neighbors for different distances can be defined as well. For the eight connected pixels, the locations are $(i - 1, j - 1)$, $(i - 1, j)$, $(i - 1, j + 1)$, $(i, j + 1)$, $(i + 1, j + 1)$, $(i + 1, j)$, $(i + 1, j - 1)$, and $(i, j - 1)$, respectively, as shown in Fig. 45. The central pixel has a gray value q , and the

Fig. 45 LBP coding: a central pixel q , the gray value of which is 6 has eight neighbors with gray values $P_0 = 4, p_1 = 6, p_2 = 9, p_3 = 4, p_4 = 2, p_5 = 6, p_6 = 9$, and $p_7 = 9$. A new mask with 8 bits is built where $t_i = 1$ if $P_i \geq q$; otherwise, $t_i = 0$. The LBP code is computed as $\sum_i t_i 2^i$; in this example, the code is 230

neighbors have gray values p_i , for $i = 0 \dots 7$. The code is computed by

$$y = \sum_{i=0}^7 t_i 2^i, \quad (61)$$

where $t_i = 1$ if $P_i \geq q$ otherwise $t_i = 0$. That means, a pixel q with its neighbors can be coded as a number $y \in \{0 \dots 255\}$. The code can be represented as a string of bits as shown in Fig. 45.

Mapping We can observe that the code generated by the previous step can be categorized according to number of changes (e.g., from “1” to “0,” or from “0” to “1”) in a cycle. For instance, in the example of Fig. 45, where the code is 01100111, we define a cycle with eight transitions as $0 \rightarrow 1 \rightarrow 1 \rightarrow 0 \rightarrow 0 \rightarrow 1 \rightarrow 1 \rightarrow 0$ (the last bit is the

repetition of the first one because it is a cycle). The number of changes is $U = 4$. Thus, we can have codes with $U = 0, 2, 4, 6$, and 8 as illustrated in Fig. 46. After the authors, there are *uniform* and *non-uniform* patterns. The first ones ($U = 0$ and 2) correspond to textures with a low number of changes, whereas the last ones ($U > 2$) can be interpreted as noise because there are many changes in the gray values. There are 58 uniform patterns and 198 nonuniform patterns. Each uniform code is mapped as a number from 0 to 57 as illustrated in Fig. 46, whereas all nonuniform codes are mapped as number 58. This descriptor is known as LBP-u2. LBP-u2 mapping corresponds to a mapping that varies with the orientation of the image, i.e., it is not rotation invariant. In order to build a rotation-invariant LBP descriptor, all patterns that have the same structure but with different rotations are mapped as a unique number. For instance, all patterns of the second row of Fig. 46 are mapped with the same number.

Fig. 46 LBP mapping for eight neighbors. Each small circle represents a bit t_i of the code, green means “1,” and white means “0.” U is the number of changes from “1” to “1,” or from “0” to “1” in one cycle. For a small number of changes, i.e., $U = 0$ and 2, the codes represent *uniform patterns*; for $U > 2$, the patterns are *nonuniform*

The same is valid for the third row. In this mapping, we have 36 different numbers. This descriptor is known as LBP-ri.

Histogram The process of coding and mapping is performed at each pixel of the input image. Thus, each pixel is converted into a number from 0 to $M - 1$, with a mapping of M numbers. Afterward, a histogram of M bins of this image is computed. The LBP descriptor of the image is this histogram.

LBP is very robust in terms of grayscale and rotation variations.^[53] An example is shown in Fig. 47. Other LBP features such as *semantic LBP*^[54] can be used in order to bring together similar bins.

The reader can find a descriptor with similar properties in the work of Zhao et al.,^[55] where *local phase quantization* is proposed.

Binarized Statistical Image Features

This is a texture description based on a binary code that is computed via linear projection using independent component analysis of natural images.^[56] We tested all filters proposed by the authors; the best performance was achieved by a filter of 7×7 pixels, with a binarization of 11 bits and a normalized histogram. The size of the descriptor is 2.048. In our experiments, we call these features binarized statistical image features.

Filter Banks

Filter banks can be used to represent visual information using a transformation of the original image. In this section, we present some filters used in the detection of defects.

Fourier and Cosine Transforms

They are used in image transformations such as discrete Fourier transform (magnitude and phase), discrete cosine transform,^[27] and wavelets as Gabor features based on 2D Gabor functions (see “Gabor” section):

$$F(m, n) = \sum_{i=1}^M \sum_{k=1}^N X(i, k) e^{-2\pi j \left(\frac{(m-1)(i-1)}{N} + \frac{(n-1)(k-1)}{N} \right)} \quad (62)$$

where $j = \sqrt{-1}$. $F(m, n)$ is a complex number. It means that magnitude and phase can be used as features.

Discrete cosine transform in 2D is defined as

$$D(m, n) = \alpha_m \alpha_n \sum_{i=1}^N \sum_{k=1}^N X(i, k) \cos \left(\frac{\pi(2i-1)(m-1)}{2N} \right) \cos \left(\frac{\pi(2k-1)(n-1)}{2N} \right) \quad (63)$$

where $\alpha_1 = \frac{1}{\sqrt{N}}$ and $\alpha_m = \sqrt{2/N}$, for $m = 2 \dots N$. Discrete cosine transform features are real numbers instead of complex number such as Fourier features.

It is worth mentioning that these features are not rotation invariant; however, we can extract rotation-invariant features if we use maximum, minimum, and a range of them.

Gabor

The Gabor functions are Gaussian-shaped band-pass filters, with dyadic treatment of the radial spatial frequency range and multiple orientations, which represent an appropriate choice for tasks requiring simultaneous measurement in both space and frequency domains. The Gabor functions are a complete (but a nonorthogonal) basis set given by

$$f(x, y) = \frac{1}{2\pi\sigma_x\sigma_y} \exp \left(-\frac{1}{2} \left(\frac{x^2}{\sigma_x^2} + \frac{y^2}{\sigma_y^2} \right) \right) \quad (64)$$

where σ_x and σ_y denote the Gaussian envelopes along the x and y axes, and u_0 defines the radial frequency of the Gabor function. Examples of Gabor functions are illustrated in Fig. 48. In this case, a class of self-similar functions are generated by rotation and dilation of $f(x, y)$.

Fig. 47 Comparison of six textures using LBP-ri descriptor. It is clear that descriptors of the same texture are very similar, and descriptors of different textures are very different. A measurement of the Euclidean distance between all six descriptors is shown in the right color matrix

Fig. 48 Example of Gabor functions in spatial domain: top) imaginary components of self-similar filter bank by using $p = 1 \dots 8$ scales and $q = 1 \dots 8$ orientations; bottom) 3D representations of two Gabor functions of (a)

Each Gabor filter has a real and an imaginary component that are stored in $M \times M$ masks, called $\mathbf{R}_{pq}$ and $\mathbf{I}_{pq}$, respectively, where $p = 1 \dots S$, denoting the scale, and $q = 1 \dots L$, denoting the orientation (for details, see the work of Kamm^[57]). Usually, $S = \text{eight scales}$, and $L = \text{eight orientations}$ as shown in Fig. 48, with $M = 27$.

The Gabor filters are applied to each segmented window $\mathbf{W}$, which contains the segmented region and its surrounding (see Fig. 39). The filtered windows $\mathbf{G}_{pq}$ are computed using the 2D convolution (Eq. 9) of the window $\mathbf{W}$ of the X-ray image with the Gabor masks as follows:

$$\mathbf{G}_{pq} = \left[\left(\mathbf{W} * \mathbf{R}_{pq} \right)^2 + \left(\mathbf{W} * \mathbf{I}_{pq} \right)^2 \right]^{\frac{1}{2}} \quad (65)$$

The Gabor features, denoted by g_{pq} , are defined as the average output of $\mathbf{G}_{pq}$, i.e., it yields $S \times L$ Gabor features for each segmented window:

$$g_{pq} = \frac{1}{n_w n_w} \sum_{i=1}^{n_w} \sum_{j=1}^{m_w} G_{pq}(i, j) \quad (66)$$

where the size of the filtered windows $\mathbf{G}_{pq}$ is $n_w \times m_w$.

Three additional Gabor features can be extracted: (i) maximum of all Gabor features: $g_{\max} = \max(\mathbf{g})$, (ii) minimum of all Gabor features: $g_{\min} = \min(\mathbf{g})$, and (iii) range of all Gabor features: $g_{\Delta} = g_{\max} - g_{\min}$. These features are very useful because they are rotation invariant.

Local Descriptors

Descriptors have been very relevant to computer vision applications.^[58] This is because they are able to provide highly distinctive features and can be used in applications such as multiple view analysis, object recognition, texture recognition, and others. In this section, we provide some descriptors that are very useful in X-ray testing.

Scale Invariant Feature Transform

The scale-invariant feature transform descriptors are local features based on the appearance of the object. The descriptors are invariant to scale, rotation, lighting, noise, and minor changes in viewpoint.^[59] In addition, they are highly distinctive and relatively easy to extract and match against a (large) database of local features. The SIFT descriptor consists of a 128-element vector, which corresponds to a set of 16 gradient-oriented histograms of eight bins distributed in a 4×4 grid.

Speeded Up Robust Feature

The speeded up robust feature (SURF) is based on the sum of the Haar wavelet response in 4×4 square subregions of the patch.^[60] Similar to SIFT, the SURF descriptor is invariant to scale and rotation. The descriptor has 64 elements.

Histogram of Oriented GRADIENTS

Histogram of oriented gradients is a descriptor that contains histograms of oriented gradients in cells distributed in a grid manner across the image.^[61]

Binary Robust Invariant Scalable Keypoint

The binary robust invariant scalable keypoint is a descriptor composed as a binary string by concatenating the results of simple brightness comparison tests using a circular sampling pattern.^[62] The descriptor has 64 elements.

Sparse Representation

In the sparse representation approach, a dictionary is built from the learning images, and testing is done by reconstructing the testing image using a sparse linear combination of the atoms of the dictionary. The testing image is assigned to the class with the minimal reconstruction error.^[2] We tested two well-known sparse representation approaches. In the first one, the dictionary is the gallery of training images itself.^[23] In the second one, the dictionary is computed from the training images using KSVD algorithm,^[63] an algorithm for creating overcomplete dictionaries based on K -means and singular value decomposition.

Deep Models

In recent years, deep learning has been successfully used in image and video recognition (see, e.g., the work of Noble et al,^[1] Mery and Filbert^[21] and Kannala and Rahtu^[22]), and it has been established as the state of the art in many areas of computer vision. The key idea of deep learning is to replace *handcrafted* features with features that are *learned* efficiently using a hierarchical feature extraction approach. There are several deep architectures such as deep neural networks, convolutional neural networks, energy-based models, Boltzmann machines, and deep belief networks, among others.^[21] Convolutional neural network (CNN), originally inspired by a biological model,^[64] is a very powerful class of methods for image recognition^[65] that replaces feature extraction and classification with a single neural network. A CNN maps an input image $\mathbf{X}$ onto an output vector $\mathbf{y} = g_L(\mathbf{X})$, where the function g_L can be viewed as a feed forward network with L layers that are typically linear operations followed by non-linearities (e.g., convolutions followed by rectified linear units^[66]). These layers f_l , for $l = 1 \dots L$, contain parameters $\mathbf{w} = (\mathbf{w}_1 \dots \mathbf{w}_l)$ that can be discriminatively learned from training data: a set of input images $\mathbf{X}_i$ and their corresponding labels $\mathbf{z}_i$, for $i = 1 \dots n$, so that $\sum_i \ell(g_L(\mathbf{X}_i), \mathbf{z}_i) / n \rightarrow \min$, where ℓ is a loss function. This optimization problem can be solved using the back-propagation algorithm.^[67] A deep learning model with 10 layers, called Xnet, for defect detection in aluminum castings was recently proposed in

[XX], however, in the experiments LBP features carried out better performance as illustrated in next section.

[XX] Mery, D.; and Arteta, C. Automatic Defect Recognition in X-ray Testing using Computer Vision. In 2017 IEEE Winter Conference on Applications of Computer Vision (WACV2017), 2017.

Example

For the detection task, two general approaches can be used: a traditional image segmentation (as explained in “Segmentation” section) or a *sliding window* approach. In the first case, image processing algorithms are used (e.g., histograms, edge detection, morphological operations, filtering, etc.^[27]). Nevertheless, inherent limitations of traditional segmentation algorithms for complex tasks and increasing computational power have fostered the emergence of an alternative approach based on the so-called sliding window paradigm. Sliding window approaches have established themselves as the state of the art in computer vision problems where a visually complex object must be separated from the background (see, e.g., successful applications in face detection^[68] and human detection^[69]). In the sliding window approach, a detection window is moved over an input image in both horizontal and vertical directions, and for each localization of the detection window, a classifier decides to which class the corresponding portion of the image belongs according to its features. Here, a set of candidate image areas are selected, and all of them are fed to the subsequent parts of the image analysis algorithm. This resembles a brute force approach where the algorithm explores a large set of possible segmentations, and at the end, the most suitable is selected by the classification steps.

An example for casting inspection using sliding windows is presented as follows: from a dataset containing around 47,500 cropped X-ray images of 32×32 pixels with defects and no defects in aluminum wheels, we defined a training and testing dataset. We extracted LBP features from each cropped image, and we trained a support vector machine. In order to illustrate the effectiveness of the use of this approach based on descriptors, we implemented a very simple sliding window strategy for a whole X-ray image that was not used in the training set. Figure 49 shows the obtained results. In this case, the size of the sliding window

Fig. 49 Defect detection in an X-ray image using a sliding window approach: left) original image with a small defect (see arrow); middle) heat map after sliding-window; c) detection by thresholding the heat map

is 32×32 pixels, i.e., the size of the cropped images of the dataset. We observe that the small defect present at the edge of the regular structure (see arrow in the left image) could be detected perfectly. In this implementation, the size of the image is 140×200 pixels, and the step of the sliding window process was one pixel. The heat map of this detection, obtained by superimposing Gaussian masks when a detection window is classified as “defect,” is illustrated in the middle image. Evidently, a more robust sliding window strategy must be tested at different scales in which saliency maps can be used to prefilter false detection and to reduce the search space of candidate sliding windows. An evaluation on a broader data base is necessary.

MULTIPLE VIEW ANALYSIS

In this section, we present a method for the automated detection of flaws based on the *tracking principle* in an X-ray image sequence: first, it identifies the potential defects in each image of the sequence, and second, it matches and tracks these from image to image. The key idea is to consider as false alarms those potential defects that cannot be tracked in the sequence.^[13] The method for automated flaw detection presented here has basically two steps (see Fig. 50): *identification* and *tracking of potential flaws* (based on a geometric model and multiple view analysis) (Figs. 51 and 52). These will be described in this section.

Geometric Model

The X-ray image of a test object corresponds to a projection in perspective, where a 3D point of the test object is viewed as a pixel in the digital X-ray image, as illustrated in Fig. 53. A geometric model that describes this projection can be very useful for 3D reconstruction and for data association between different views of the same object. Thus, 3D features or multiple view 2D features can be used to improve the diagnosis performed by using a single view.

For the geometric model, four coordinate systems are used (see Fig. 53):

- OCS (X, Y, Z): Object Coordinate System, where a 3D point is defined using coordinates attached to the test object.
- WCS ($\bar{X}, \bar{Y}, \bar{Z}$): World Coordinate System, where the origin corresponds to the optical center (X-ray source) and the $\bar{Z}$ axis is perpendicular to the projection plane of the detector.
- Projection coordinate system (PCS) (x, y) where the 3D point is projected into projection plane $\bar{Z} = f$, and the origin is the intersection of this plane with $\bar{Z}$ axis.
- Image coordinate system (ICS) (u, v), where a projected point is viewed in the image. In this case, (x, y) axes are set to be parallel to (u, v) axes.

Fig. 50 Automated flaw detection in aluminum castings based on the tracking of potential defects in an X-ray image sequence. PF = potential flaws; RS = potential flaws classified as regular structures; F = detected flaws^[13]

Fig. 51 X-ray image C0001_0030 of an aluminum wheel (see zoom in Fig. 52)

Fig. 52 Zoom of Fig. 51 and gray-level profile along three rows crossing defects

Fig. 53 Geometric model: a 3D point (X, Y, Z) is projected as a 2D point (u, v)

The geometric model $OCS \rightarrow ICS$, i.e., transformation $\mathbf{P}: (X, Y, Z) \rightarrow (u, v)$, can be expressed in homogeneous coordinates as^[70]

$$\lambda \begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \mathbf{P} \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix}, \quad (67)$$

where λ is a scale factor and $\mathbf{P}$ is a 3×4 matrix modeled as the following three transformations:

- $OCS \rightarrow ICS$, i.e., transformation $\mathbf{T}_1: (X, Y, Z) \rightarrow (\bar{X}, \bar{Y}, \bar{Z})$, using a 3D rotation matrix $\mathbf{R}$ and a 3D translation vector $\mathbf{t}$
- $WCS \rightarrow (PCS)$, i.e., transformation $\mathbf{T}_2: (\bar{X}, \bar{Y}, \bar{Z}) \rightarrow (x, y)$, using a perspective projection matrix that depends on focal distance f

- $PCS \rightarrow ICS$, i.e., transformation $\mathbf{T}_3: (x, y) \rightarrow (u, v)$, using scales factor α_x and α_y , and a 2D translation vector (u_0, v_0) .

The three transformations $OCS \rightarrow WCS \rightarrow PCS \rightarrow ICS$ are expressed as

$$\mathbf{P} = \underbrace{\begin{bmatrix} \alpha_x & 0 & u_0 \\ 0 & \alpha_y & v_0 \\ 0 & 0 & 1 \end{bmatrix}}_{\mathbf{T}_3} \underbrace{\begin{bmatrix} f & 0 & 0 & 0 \\ 0 & f & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}}_{\mathbf{T}_2} \underbrace{\begin{bmatrix} \mathbf{R} & \mathbf{t} \\ \mathbf{0}^T & 1 \end{bmatrix}}_{\mathbf{T}_1} \quad (68)$$

The parameters included in matrix $\mathbf{P}$ can be estimated using a calibration approach as illustrated in Fig. 54.^[38]

In order to obtain multiple views of the object, m different projections of the test object can be achieved by

Fig. 54 Geometric calibration of a computer vision X-ray imaging system: the modeled projection of a 3D model coincides with real geometry of the calibration object

rotating and translating it (for this task a manipulator can be used as shown in Fig. 55). For the k th projection, for $k = 1 \dots m$, the geometric model $\mathbf{P}_k$ used in Eq. 67 is computed from Eq. 68 including a 3D rotation matrix $\mathbf{R}_k$ and a 3D translation $\mathbf{t}_k$.

Our strategy deals with detections in multiple views. In this problem of data association, the aim is to find the correct correspondence among different views. For this reason, we use multiple view geometric constraints to reduce the number of matching candidates between monocular detections. In our approach, the geometric constraints are established from bifocal (epipolar) and trifocal geometries.^[38] Thus, for a point $\mathbf{x}_i$ in view $\mathbf{I}_i$, the corresponding point $\mathbf{x}_j$ in a second view $\mathbf{I}_j$ must lie on its *epipolar line* estimated by using the bifocal tensors (or fundamental matrix) $\mathbf{F}_{ij}$ of views i and j . On the other hand, for a point $\mathbf{x}_i$ in view $\mathbf{I}_i$ and

its corresponding point $\mathbf{x}_j$ in view $\mathbf{I}_j$, the corresponding point $\mathbf{x}_k$ in a third view $\mathbf{I}_k$ is a point estimated by using the trifocal tensors $\mathbf{T}_{ijk}$ of views i , j , and k . Multifocal tensors can be estimated from projection matrices $\mathbf{P} = \{\mathbf{P}_i\}_{i=1}^m$, where $\mathbf{P}_i$ is used to calculate the projection of a (3D) point $\mathbf{X}$ of the test object into a (2D) point $\mathbf{x}_i$ of image $\mathbf{I}_i$. The projection is computed as $\lambda \mathbf{x}_i = \mathbf{P}_i \mathbf{X}$ using homogeneous coordinates, where λ is a scale factor. The fundamental matrix $\mathbf{F}_{ij}$ is calculated from $\mathbf{P}_i$ and $\mathbf{P}_j$, and the trifocal tensors $\mathbf{T}_{ijk}$ from $\mathbf{P}_i$, $\mathbf{P}_j$, and $\mathbf{P}_k$ (see details in the work of Nair and Hinton^[38]).

The estimation of $\mathbf{P}$ can be performed by minimizing the error between real and modeled projection $3D \rightarrow 2D$. Two well-known approaches can be used: (i) *calibration*, in which known 3D points from a calibration object are used^[38,70] or (ii) *bundle adjustment*, in which both 3D points and projection matrices are calculated from the views of

Fig. 55 Generally a manipulator is used to locate the test object in a desired position

the test object itself using stable tracked keypoints across multiple views.^[71,72]

Identification of Potential Flaws

A digital X-ray image sequence of the object test is acquired (see, e.g., series C0001 of GDxray^[6]). In order to ensure the tracking of flaws in the X-ray images, similar projections of the specimen must be achieved along the sequence. For this reason, the sequence consists of X-ray images taken by the rotation of the casting at small intervals (e.g., 5°). Since many images are captured, the time of the data acquisition is reduced by taking the images without frame averaging. The position of the casting, provided online by the manipulator, is registered at each X-ray image to calculate the perspective projection matrix $\mathbf{P}_p$ of image p of the sequence (for details, see “Geometric Model” section). An X-ray image sequence is shown in Fig. 56.

The detection of potential flaws identifies regions in X-ray images that may correspond to real defects. This process takes place in each X-ray image of the sequence without considering information about the correspondence between them. Two general characteristics of the defects are used for identification purposes: (i) a flaw can be considered as a connected subset of the image, and (ii) the gray-level difference between a flaw and its neighborhood is significant. However, as the signal-to-noise ratio in our X-ray images is low, the flaw signal is slightly greater than the background noise, as illustrated in Fig. 52. In our experiments, the mean gray level of the flaw signal (without background) was between 2.4 and 28.8 gray values with a standard deviation of 6.1. Analyzing a homogeneous background in different areas of interest of normal parts, we found that the noise signal was within ± 13 gray values with a standard deviation of 2.5. For this reason, the identification of real defects with poor contrast can also involve the detection of false alarms.

According to the mentioned characteristics of the real flaws, our method of identification has the following two

steps (see Fig. 42): edge detection and segmentation and classification of potential flaws. In this case, the approach based on CLPs can be used (see “Crossing Line Profiles” section). A statistical study of the classification of potential flaws using more than 70 features can be found in the work of Faugeras.^[48]

This is a very simple detector of potential flaws. However, the advantages are as follows: (i) it is a single detector (it is the same detector for each image), and (ii) it is able to identify the potential defects independent of the placement and the structure of the specimen.

Using this method, some real defects cannot be identified in all X-ray images in which they appear if the contrast is very poor or the flaw is not enclosed by edges. For example, in Fig. 57, one can observe that the biggest real flaw was identified in images 1, 2, 3, 4, and 6, but not in image 5 where only two of the three real flaws were identified (compare with Fig. 52). Additionally, if a flaw is overlapped by the edges of the structure of the casting, not all edges of the flaw can be detected. In this case, the flaw will not be enclosed and therefore not be segmented. Furthermore, a small flaw that moves in front (or behind) of a thick cross section of the casting, in which the X-rays are highly absorbed, may cause an occlusion. In our experiments, this detector identified the real flaws in four or more (not necessarily consecutive) images of the sequence.

Tracking of Potential Defects with Multiple View Analysis

In the previous step, n_1 potential regions were segmented and described in the entire image sequence $\mathbf{I}$. Each segmented region is labeled with a unique number $r \in \mathbf{T}_1 = \{1, \dots, n_1\}$. In view i , there are m_i segmented regions that are arranged in a subset $\mathbf{t}_i = \{r_{i,1}, r_{i,2}, \dots, r_{i,m_i}\}$, i.e., $\mathbf{T}_1 = \mathbf{t}_1 \cup \mathbf{t}_2 \cup \dots \cup \mathbf{t}_m$. The matching and tracking algorithms combine all regions to generate consistent tracks of the object's parts of interest across the image sequence. The algorithm has the following steps:

Fig. 56 X-ray image sequence with three flaws (image 5 is shown in Fig. 52)

Fig. 57 Identification of potential flaws (the arrows indicate real flaws)

Matching in two views: All regions in view i that have corresponding regions in the next p views are searched, i.e., regions $r_1 \in \mathbf{t}_i$ that have corresponding regions $r_2 \in \mathbf{t}_j$ for $i = 1, \dots, m-1$ and $j = i+1, \dots, \min(i+p, m)$. In our experiments, we use $p = 3$ to reduce the computational cost. The matched regions (r_1, r_2) are those that meet *similarity* and *location* constraints. The similarity constraint means that corresponding descriptors $\mathbf{y}_{r_1}$ and $\mathbf{y}_{r_2}$ must be similar enough such that

$$\|\mathbf{y}_{r_1} - \mathbf{y}_{r_2}\| < \varepsilon_1. \quad (69)$$

The location constraint means that the corresponding locations of the regions must meet the epipolar constraint. In this case, the Sampson distance between $\mathbf{x}_{r_1}$ and $\mathbf{x}_{r_2}$ is used, i.e., the first-order geometric error of the epipolar constraint must be small enough such that

$$\left\| \mathbf{x}_{r_2}^T \mathbf{F}_{ij} \mathbf{x}_{r_1} \right\| \left(\frac{1}{\sqrt{a_1^2 + a_2^2}} + \frac{1}{\sqrt{b_1^2 + b_2^2}} \right) < \varepsilon_2, \quad (70)$$

with $\mathbf{F}_{ij} \mathbf{x}_{r_1} = [a_1 \ a_2 \ a_3]^T$ and $\mathbf{F}_{ij}^T \mathbf{x}_{r_2} = [b_1 \ b_2 \ b_3]^T$. In this case, $\mathbf{F}_{ij}$ is the fundamental matrix between views i and j calculated from projection matrices $\mathbf{P}_i$ and $\mathbf{P}_j$ ^[38] (see “Geometric Model” section). In addition, the location constraint used is as follows:

$$\|\mathbf{x}_{r_1} - \mathbf{x}_{r_2}\| < \rho(j-i), \quad (71)$$

because the translation of the corresponding points in these sequences is smaller than that of ρ pixels in consecutive frames.

If we have 3D information about the space where our test object should be, it is worth evaluating whether the 3D point reconstructed from the centers of mass of the regions must belong to the space occupied by the casting. From $\mathbf{m}_p^a$ and $\mathbf{m}_q^b$, the corresponding 3D point $\hat{\mathbf{M}}$ is estimated using the linear approach of Hartley in the work

of Gonzalez and Woods.^[73] For two views, this approach is faster than the least squares technique. It is necessary to examine if $\hat{\mathbf{M}}$ resides in the volume of the casting, the dimensions of which are usually known a priori (e.g., a wheel is assumed to be a cylinder).^e

Finally, a new matrix $\mathbf{T}_2$ sized $n_2 \times 2$ is obtained with all matched duplets (r_1, r_2) , one per row. If a region is found to have no matches, it is eliminated. Multiple matching, i.e., a region that is matched with more than one region, is allowed. Using this method, problems such as non-segmented regions or occluded regions in the sequence can be solved by tracking if a region is not segmented in consecutive views.

Matching in three views: Based on the matched regions stored in matrix $\mathbf{T}_2$, we look for triplets (r_1, r_2, r_3) , with $r_1 \in \mathbf{t}_i, r_2 \in \mathbf{t}_j, r_3 \in \mathbf{t}_k$ for views i, j , and k . We know that a row a in matrix $\mathbf{T}_2$ has a matched duplet $[\mathbf{T}_2(a, 1) \ \mathbf{T}_2(a, 2)] = [r_1 \ r_2]$. We then look for row b in $\mathbf{T}_2$ in which the first element is equal to r_2 , i.e., $[\mathbf{T}_2(b, 1) \ \mathbf{T}_2(b, 2)] = [r_2 \ r_3]$. Thus, a matched triplet (r_1, r_2, r_3) is found if the regions r_1, r_2 , and r_3 meet the trifocal constraint:

$$\|\hat{\mathbf{x}}_{r_3} - \mathbf{x}_{r_3}\| < \varepsilon_3, \quad (72)$$

This means that $\mathbf{x}_{r_3}$ must be similar enough to the reprojected point $\hat{\mathbf{x}}_{r_3}$ computed from the points in views i and j ($\mathbf{x}_{r_1}$ and $\mathbf{x}_{r_2}$), and the trifocal tensors $\mathbf{T}_i^{jk}$ of views i, j , and k calculated from projection matrices $\mathbf{P}_i, \mathbf{P}_j$, and $\mathbf{P}_k$ ^[38] (see “Geometric Model” section). A new matrix $\mathbf{T}_3$ sized $n_3 \times 3$ is built with all matched triplets (r_1, r_2, r_3) , one per row. Regions in which the three views do not match are eliminated. The results of our example are shown in Fig. 58.

^eIt is possible to use a CAD model of the casting to evaluate this criterion more precisely. Using this model, we could discriminate a small hole of the regular structure that is identified as a potential flaw. Additionally, the CAD model can be used to inspect the casting geometry, as shown in the work of Teh and Chin.^[63]

Fig. 58 Matching of potential flaws in two views

Matching in more views: For $v = 4, \dots, q < m$ views, we can build the matrix recursively $\mathbf{T}_v$, sized $n_v \times v$, with all possible v -tuples $(r_1, r_2, \dots, r_v)$ that fulfill $[\mathbf{T}_{v-1}(a, 1) \dots \mathbf{T}_{v-1}(a, v-1)] = [r_1 \ r_2 \ \dots \ r_{v-1}]$ and $[\mathbf{T}_{v-1}(b, 1) \dots \mathbf{T}_{v-1}(b, v-1)] = [r_2 \ \dots \ r_{v-1} \ r_v]$, for $j, k = 1, \dots, n_{v-1}$. No more geometric constraints are required because it is redundant. The final result is stored in matrix $\mathbf{T}_q$. For example, for $q = 4$ we store

in matrix $\mathbf{T}_4$ the matched quadruplets (r_1, r_2, r_3, r_4) with $r_1 \in t_i, r_2 \in t_j, r_3 \in t_k, r_4 \in t_l$ for views i, j, k , and l .

Figure 59 shows the tracked regions of our example that fulfill this criterion. Only two false trajectories are observed (see arrows).

As our detector cannot guarantee the identification of all real flaws in more than four views, a tracking in five

Fig. 59 Tracking in more views (the arrows indicate false detections)

views could lead to the elimination of those real flaws that were identified in only four views. However, if a potential flaw is identified in more than four views, more than one quadruplet can be detected. For this reason, these corresponding quadruplets are joined in a trajectory that contains more than four potential flaws (see trajectory with arrows in Fig. 59).

The matching condition for building matrix $\mathbf{T}_i$, $i = 3, \dots, q$, is efficiently evaluated (avoiding an exhaustive search) by using a k - d tree structure^[75] to search the nearest neighbors for zero Euclidean distance between the first and last $i - 2$ columns in $\mathbf{T}_{i-1}$.

Merging tracks: Matrix $\mathbf{T}_q$ defines the tracks of regions in q views. It can be observed that some of these tracks correspond to the same region. For this reason, it is possible

to merge tracks that have $q - 1$ common elements. In addition, if a new track has more than one region per view, we can select the region that shows the minimal reprojection error after computing the corresponding 3D location. In this case, a 3D reconstruction of $\hat{\mathbf{X}}$ is estimated from tracked points.^[38] Finally, matrix $\mathbf{T}_m$ is obtained with all merged tracks in the m views. See an example of the whole tracking algorithm in Fig. 60.

Analysis: The 3D reconstructed point $\hat{\mathbf{X}}$ from each set of tracked points of $\mathbf{T}_m$ can be reprojected in views where the segmentation may have failed to obtain the complete track in all views. The reprojected points of $\hat{\mathbf{X}}$ should correspond to the centroids of the non-segmented regions. It is then possible to calculate the size of the projected region as an average of the sizes of the identified regions in the

Fig. 60 Tracking example with $m = 6$ views. In each view, there are 2, 4, 2, 2, 3, and 3 segmented regions, i.e., there are $n_1 = 16$ regions in total. For each region, we seek the corresponding regions in the next $p = 3$ views (see matching arrows in $\mathbf{T}_1$ region 1 with regions (3, 4, 5, 6) in view 2, regions (7, 8) in view 3, and (9, 10) in view 4). We observe that after tracking in 2, 3 and 4 views, there are only two tracks in $\mathbf{T}_6$ that could be tracked in 5 and 4 views, respectively. The regions that were not segmented can be recovered by reprojection (see gray circles in views 2, 4, and 6). Finally, each set of tracked regions is analyzed in order to take the final decision

track. In each view, a small window centered in the computed centroids is defined. These corresponding small windows, referred to as *tracked part*, will be denoted as $\mathbf{W} = \{\mathbf{W}_1, \dots, \mathbf{W}_m\}$. In each view, a small window is defined with the estimated size in the computed centers of gravities (see Fig. 61). Afterward, the corresponding windows are averaged. Thus, the attempt is made to increase the signal-to-noise ratio by the factor $\sqrt{n}$, where n is the number of averaged windows. As flaws must appear as contrasted zones relating to their environment, we can verify if the contrast of each averaged window is $>2.5\%$. With this verification, it is possible to eliminate all remaining false detections. Figure 61 shows the detection in our sequence using this method. Our objective is then achieved: the real defects were separated from the false ones.

Experimental Results

In this section, the results of automatic inspection of cast aluminum wheels using the outlined approach are presented. These results have been achieved recently on synthetic flaws and real data. The parameters of our method have been manually tuned, giving $\sigma = 1.25$ pixels (for LoG operator), $\varepsilon_2 = 0.75$ mm, $\varepsilon_s = 0.7$ mm, and $\varepsilon_3 = 0.9$ mm. These parameters were not changed during these experiments. A wheel was considered to be a cylinder with the following dimensions: 470 mm diameter and 200 mm height. The focal length (distance between the X-ray source and the entrance screen of the image intensifier) was 884 mm. The bottom of a wheel was 510 mm from the

X-ray source. Thus, a pattern of 1 mm in the middle of the wheel is projected in the X-ray projection coordinate system as a pattern of 1.73 mm and in the image coordinate system as a pattern of 2.96 pixels. The sequences of X-ray images were taken by rotation of the casting at 5° .

The detection performance will be evaluated by computing the number of true positives (TP) and false positives (FP). They are respectively defined as the number of flaws that are correctly classified and the number of misclassified regular structures. The TP and FP will be normalized by the number of existing flaws (E) and the number of identified potential flaws (I). Thus, we define the following percentages: $TPP = TP/E \times 100$ and $FPP = FP/I \times 100$. Ideally, $TPP = 100\%$ and $FPP = 0\%$.

Synthetic flaws: To evaluate the performance of our method in critical cases, real data in which synthetic flaws have been added were examined. A simple 3D modeled flaw (a spherical bubble) was projected and superimposed on real X-ray images of an aluminum wheel according to the law of X-ray absorption.^[76] In our experiment, a flaw is simulated in 10 X-ray images of a real casting, in an area that included an edge of the structure (see Fig. 62a). In this area, the synthetic flaw was located in 24 different positions in a regular grid manner. At each position, TPP and FPP were tabulated. This test was repeated for different sizes of the flaws ($\varnothing = 1.5 \sim 7.5$ mm) which are illustrated in Fig. 62b. The results are shown in Fig. 62c. It was observed that the FPP was always zero. The TPP was 100% for $\varnothing \geq 2.5$ mm and $>95\%$ for $\varnothing \geq 2.1$ mm. However, the identification of the flaw may fail (and therefore also its

Fig. 61 Reconstruction and verification: the false detections (indicated by the arrows) are eliminated after the verification in all images of the sequence

Fig. 62 Detection on synthetic flaws: a) X-ray image and evaluated area; b) flaw sizes; c) TPP and FPP

detection) if it is very small and is located at the edge of the structure of the casting. In this case, one may choose a smaller value of the parameter σ in the LoG operator of the edge detection, which will unfortunately increment the FPP. Other noncritical experiments, where the area of the simulation does not include an edge of the structure, have led to perfect results (TPP = 100%, FPP = 0%) for $\varnothing \geq 1.5$ mm (≥ 4.4 pixels). Usually, the minimum detectable defect size according to inspection specifications is on the order of $\varnothing = 2$ mm. In X-ray testing, smaller flaws can

be detected by decreasing the distance of the object test to the X-ray source.

Real data: Fourteen X-ray image sequences of aluminum wheels with 12 known flaws were inspected. Three of these defects were existing blow holes (with $\varnothing = 2.0 - 7.5$ mm). They were initially detected by a visual (human) inspection. The remaining nine flaws were produced by drilling small holes ($\varnothing = 2.0 - 4.0$ mm) in positions of the casting that were known to be difficult to detect. Casting flaws are present only in the first seven sequences. The results are summarized in Table 2 and Figs. 63 and 64. In the identification of potential flaws, it was observed that the FPP was 98% (4310/4381). Nevertheless, the TPP in this experiment was good, and it was possible to identify 85% (71/84) of all projected flaws in the sequences (13 of the existing 84 flaws were not identified because the contrast was poor or they were located at the edges of regular structures). It was observed that in the next steps, the FPP was reduced to zero. The detection of the real flaws was successful in all cases. The first six images of sequence 3 and its results were already illustrated in Figs. 56–61. The results on the other sequences with flaws are shown in Fig. 63.

Comparison with other methods: In this section, we present a comparison of our proposed algorithm with other methods that can be used to detect defects in aluminum castings. In this comparison, we evaluate the same real 14 sequences used in the previous section. The results are summarized in Table 3.

First, we compared the first step of our method (*identification of potential flaws*). The objective of this step is the use of a single filter, instead of a set of filters adapted to the regular structure of the specimen. We evaluated the

Table 2 Detection of flaws on real data

Sequence	X-ray images	Flaws in the sequence	Flaws in the images (E)	Identification			Detection	
				TP	FP	Total (I)	TP	FP

Proposed	85	98	100	0

well-known Canny filter (see, e.g., the work of Hu^[14]). As this filter detected sparse edge pixels that did not necessarily produce at real flaws closed and connected contours, the TPP of this detector was unacceptable, and only 4% of the real flaws were identified (“Canny I” in Table 3). In order to increase the number of closed regions, a dilation of the edges using a 3×3 mask was performed. Although

the TPP is improved to 40% (“Canny II” in Table 3), many flaws were not detected in any of the images of the sequence. For this reason, only 17% of the real flaws were detected after the tracking and verification.

Another detection of potential flaws can be performed using a region-based segmentation. Median filtering is normally used to generate an error-free image,

since defect structures are essentially eliminated, while design features of the test piece are normally preserved^[51]. Once the error-free reference image is computed, an error difference image between the original and error-free images is calculated. Casting defects are then identified when a sufficiently large gray level in the error difference image occurs. The best results were obtained using a median filter with an 11×11 mask. We evaluated two thresholds: $\theta = 6$ and $\theta = 2$ -by-256 gray levels (see “Median I” and “Median II” in Table 3). In the first case, the TPP was only 55%. By decreasing the threshold value, we increased the TPP to 88%, which is slightly better than our detector (85%). However, systematic false alarms were detected at the corners of the regular structures. Since these false alarms satisfy the multifocal conditions, they can be tracked in the sequence. For this reason, this detector can only be used if the median filter is adapted to the regular structures of the specimen using a priori information. Normally, a set of median filters are used for each X-ray image.^[77–79]

In order to evaluate the second step of our method (*tracking of potential flaws*), we tested the method by tracking the potential flaws in three and five views, instead of four views (see “Tracking in 3,” “Tracking in 5,” and “Proposed” in Table 3). By considering only three views, we obtained so many false alarms that the verification step detected four false alarms (25%). In the other case, by tracking the potential flaws in five views, real flaws that were segmented in only four views of the sequences were not tracked. For this reason, only 83% of the real flaws were detected.

Finally, we inspected the test castings using a classic image processing method. In our experiments, we used the industrial software PXV-5000.^[80,81] The results were excellent: 100% of the real flaws were detected without false alarms. As a result of its peak detection performance, the classic image processing methods have become the most widely established in industrial applications. However, these methods suffer from the complicated configuration of the filtering, which is tailored to the test piece. In our experiments, the configuration process has taken 2 weeks. Nevertheless, as our method requires only a few number of parameters, the configuration could be carried out in hours.

CONCLUSIONS

In this article, the fundamental principles of the automated detection of die casting discontinuities have been explained. A general inspection schema was presented, and several methods that have appeared in the literature in the past 30 years were explained showing the development of this sector in the areas of industry and academia. It is worth mentioning that automated defect detection in castings is very effective.

As a result of its peak detection performance, the reference inspection methods have become most widely established in industrial applications. These methods suffer from the complicated configuration of their filtering, which is tailored to the test piece. Typically, this optimization process takes 1 week, independent of whether it is performed manually or automatically.

On the other hand, the prerequisite for the use of a method with no a priori information of the piece's structure is the existence of common properties that define all casting discontinuities well and also differentiate them from design features of the test pieces. These prerequisites are often fulfilled only in special testing situations.

It is clear that the recent progress in computer technology allows the handling of various theoretical and experimental problems in science and technology, which were inaccessible before. Currently, the processing of image sequences, the use of sophisticated filters in digital image processing, and the design of new deep learning models—to cite a few—are possible. However, in order to assess the performance objectively, it will be necessary to analyze a broader databank.

Control Principle of Thermal Spray Process

Masahiro Fukumoto

Mechanical Engineering, Toyohashi University of Technology, 1-1, Tempaku-cho,
Toyohashi, 441-8580, Japan

Abstract

In general, an essential target in the research and development of material process lies in how to establish the controlling principle on a designated material process. In this article, the current situation in the controlling of an ordinary thermal spray process, which is a representative of a thick coating formation process using particle deposition, is reviewed. Precise observation results were introduced to the ordinary thermal spray process. In the flattening behavior of the sprayed particle onto the substrate surface, critical conditions were recognized in both the substrate temperature and the ambient pressure. A transition temperature, T_t , and a transition pressure, P_t , were defined and introduced, respectively, for these critical conditions. Three-dimensional transition curvature, by combining both the T_t and the P_t dependence, was proposed as a control principle of the thermal spray process. Furthermore, particle melting in the ordinary thermal spray process has been recognized as a negative process. To overcome this problem, a new direction in coating technology development by using non-fusion solid particles has been tried recently, which is typically called the cold spray or the aerosol deposition process. As these processes have common characteristic for all, namely, a thick coating formation by the deposition of several micron-sized particles, the present state of the art, academic/technological issues, and the prospects for the future of these coating formation processes is comprehensively summarized in this article.

Keywords: Aerosol deposition; Cold spray; Flattening behavior; Process control; Single splat; Thermal spray; Thick coating; Transition curvature; Warm spray.

INTRODUCTION

There exists a surface coating technology that enables the formation of thick coating with an extremely high deposition rate. A structural unit for the coating formation of the process is given as a powder particle of several microns in diameter. The process mainly covers the formation of thick coating over $10\mu\text{m}$ in thickness and has an identical domain in the coating formation compared to the normal chemical vapor deposition (CVD) or physical vapor deposition (PVD) processes, which are classified for thin films. Thermal barrier coating, commonly called TBC, on the turbine blades can be introduced as a typical product formed by the process. These thick coatings play an essential role in structural components from both a structural and a functional viewpoint, which is not always sufficiently provided by the thin films made by the PVD or CVD processes. Thus, these thick coatings are widely recognized as an essential element for various practical applications. Thermal spraying is considered to be one of the most important processes for making these thick coatings and plays an important role as a fundamental key technology in many industrial production fields, such as automotive, aircraft, and energy related.

The merits of the thermal spray process can be summarized as follows: three major industrial materials, namely, metal, ceramic, and polymer can be easily treated; any kind of material can be treated as a substrate material; the process has an extremely high deposition rate; a thick coating over $10\mu\text{m}$ thickness can be easily made; coatings can be formed in an atmosphere with or without a controlled chamber; high-quality coating with higher adhesion strength or a proper porosity can be achieved by adjusting the spray conditions; and so on. In addition to the progress in the thermal spray process itself, and due to the rapid progress of current measurement technology, in-flight measurement of the sprayed particle and feedback controlling of the process have been achieved with great success. However, since this process control is particularly recent, an optimization of the process control is strongly desired in this technology field.

In contrast, many kinds of functional materials, such as a nanostructured material, have been swiftly developed recently based on the rapid progress in advanced nanotechnology. As the development of new material requires new processes for industrial production, this in turn brings about the development of new processes. As an example, in the case of thick functional coating formation, material melting in ordinary thermal spraying sometimes destroys

Fig. 1 Process map for thick coating formation. T_m : melting point of material, RF: Radio Frequency, APS: Atmospheric Plasma Spray, LPPS: Low Pressure Plasma Spray, HVOF: High Velocity Oxy-Fuel, HVOF: High Velocity Air-Fuel

or deteriorates the material function or artificially designed nanostructure. As a result, melting itself is recognized as a negative process. To overcome this problem, a new direction in coating technology using non-fusion solid particles has been tried recently, typically by a cold spray (CS) or an aerosol deposition (AD) process. The ordinary and newly developed coating processes, based on the deposition of powder particles, are summarized in Fig. 1. The ordinary plasma spray is a typical process using melt particles for the coating formation. Alternatively, non-fusion processes, typically called CS and AD, have developed rapidly recently.

As these processes have common characteristics for all, that is, thick coating formation by the deposition of several micron-sized particles, the present state of the art, academic/technological issues, and the prospects for the future of these coating formation processes by particle deposition is comprehensively summarized in this chapter.

CURRENT SITUATION IN CONTROLLING THE ORDINARY THERMAL SPRAY PROCESS

Generally, an essential target in the research and development of material process lies in how to establish the controlling principle on the designated material process. In this section, the current situation in the controlling of the ordinary thermal spray process, which is a representative of the thick coating formation process using particle deposition, is briefly described. Here, with the ordinary thermal spray process using melt powder particles, the collision and deposition behavior of an individual particle onto the substrate surface becomes the fundamental key process to be investigated. The controlling principle may be induced by specifying the dominating factors in the

process and clarifying the effect of these dominations on the process. Recently, on the other hand, it has been realized that the detailed in-flight information of the sprayed individual particle can be captured by highly developed measurement equipment, and, by feeding back these values into the process input power, macroscopic controlling may be achieved. Instead of this macroscopic controlling, however, a microscopic control based on the observation of the actual flattening behavior of the individual sprayed particles is introduced in this section.

Critical in the Flattening Behavior of the Thermal Sprayed Particle and the Three-Dimensional Curvature for Process Control

The flattening behavior of the thermally sprayed particle impinging onto a flat substrate surface can be recognized as a fundamental phenomenon of the coating formation in the thermal spray process. Therefore, clarification of the flattening behavior of the individual particle is essential. It is assumed that the sprayed particle, having an original diameter of ϕd , flattens into a cylindrical shape with the diameter of ϕd after the impact on the flat substrate surface. The flattening degree, $\xi = D/d$, can be given theoretically as represented by Madejski's model:^[1]

$$\xi = A(\text{Re})^B$$

Here, Re is the Reynolds number of the particle, $\text{Re} = \rho v d / \eta$ that quantifies the viscous dissipation of the inertia forces, where A and B are constants. Since the Re includes ρ (density), η (viscosity), and v (velocity), where the density and viscosity are the function of the temperature, the above formula indicates that both the in-flight temperature and the velocity of the particle are the dominating factors in the flattening of the sprayed particles. This also indicates that the flattening behavior can be controlled by the in-flight particle velocity and temperature just prior to the impact on the substrate. Recently, within the thermal spray industrial field, the process control has been steadily improved by measuring the in-flight information of the particles and feeding them back into the process input power, which is enhanced by the rapid developments in measurement technology. However, the available quantitative relationship between the in-flight information of the particle and the resultant coating properties has not been clearly understood up to now; therefore, further investigation is required for future research. Based on the situation mentioned previously, the current production and quality control of the products made by thermal spraying is mostly done in an empirical manner in most of the industries around the world. Namely, lots of samples are initially fabricated by changing the dominating factors systematically, with the optimum process condition decided after several evaluation tests on the coated samples.

Instead of the particle-oriented factors, namely, the particle temperature or velocity given as the in-flight information, it has been pointed out that the particle/substrate interface-oriented factors, such as the substrate temperature and the ambient pressure, more significantly affect the flattening behavior of the sprayed particles.^[2-6] The experimental results have especially revealed that the splat shape of most metallic, polymer, and ceramic material onto a flat substrate surface has a transitional changing tendency from a distorted shape with a splash to a lenticular shape without a splash in a narrow temperature range as the substrate temperature increases, as shown in Fig. 2. The transition temperature, T_t , at which the particle splat pattern changes to the form without splashing from the form with splashing, was defined and introduced by Fukumoto.^[2] Since then, the drastic change in the splat pattern close to the transition temperature has been considered as a matter of great concern in recent years. Moreover, it was also verified experimentally that the adhesion strength of the coating changed transitionally with the increasing substrate temperature, and its dependence on the substrate temperature corresponded quite well with the splat pattern.^[3] Thus, the investigation of the flattening mechanism of the sprayed particles onto the substrate surface is particularly meaningful for the practical use of thermal spray coatings. Based on the experimental, analytical, or numerical approach, a unified explanation has been attempted on the transition behavior. As the most possible domination, such as the role of solidification in the flattening particle,^[7] wetting at the particle/substrate interface,^[5,6] and desorption of adsorbates on the substrate surface^[8] on the flattening behavior were investigated mainly.

The effect of ambient pressure on the flattening behavior of the sprayed particle was systematically investigated in low-pressure plasma spraying. The substrate temperature was kept at room temperature. From the results, it was

Fig. 2 Changing splat morphology with substrate temperature and definition of transition temperature, T_t

found that the disk shape splat appears just by reducing the ambient pressure, whereas the substrate temperature is kept constant at room temperature. The experiments also reveal that the transition behavior from the splash splat to the disk shape splat is recognized in most of the metallic materials by reducing the ambient pressure, as shown in Fig. 3. The transition pressure P_t at which the particle splat pattern changes from the splash shape splat to a disk shape splat is also defined. Transition pressure distribution for each sprayed material is summarized in Fig. 4. In the

Fig. 3 Splat morphology change with ambient pressure and definition of transition pressure, P_t

Fig. 4 Similarity in dependence of transition pressure and transition temperature on sprayed material

figure, the dependence of the transition temperature on the sprayed material is also shown for the purpose of comparison. From the figure, it is recognized that the dependence of the T_i and P_i on the particle material has quite a similar tendency. This fact indicates that both the substrate temperature and the ambient pressure may have an equivalent effect on the transition.

Figure 5 shows that the bottom surface microstructures change by changing the ambient pressure and the substrate temperature, respectively. The similar tendency of microstructural changes from the porous to the dense is observed in both cases. The dependence of the fraction of disk splat on the substrate temperature and ambient pressure is summarized schematically as shown in Fig. 6. By selecting the optimum operating conditions in both factors, one can control the coating microstructure and some other properties of the coating. Thus, the controlling of the thermal spray process can be attained by introducing both T_i and P_i as critical factors. By combining the T_i and P_i , a three-dimensional transition curvature is drawn. From a systematic investigation, a three-dimensional transition curvature is confirmed experimentally^[9,10] in various materials as shown in Fig. 7. As these databases provide a controlling principle to the thermal spray production field, the process control is already being implemented in some automobile and energy-related companies in Japan.^[11]

Clarification on Transition Mechanism

The transition mechanism has been clarified by many researchers. As a result, it is pointed out that rapid solidification at the bottom surface of the splat after collision,

Fig. 6 Concept of three-dimensional transition curvature

physical/chemical adsorbates, and condensates may induce splashing.^[12] However, some hypothesis has been given up to now that the dynamic wetting, which accompanies the transfer of both heat and material at splat/substrate interface, seems to dominate this unique phenomenon. On a fixed substrate such as AISI304 stainless steel, each sprayed material shows an individual T_i or P_i value. By summarizing these T_i or P_i values for each material, a unified rule is clarified. Consequently, it is found that the material order, as shown in Fig. 8, in T_i or P_i follows the same order as the Periodic Table. However, only Fe is an exception to this rule, since plasma-sprayed iron particle has a unique tendency in the oxidation that the oxidation may be enhanced by induced flow within the particle that sweeps away the outer layer of iron oxide and exposes new metal surface.^[13] In general, it is recognized that the thermal spray process is very complicated because many factors affect the process.

Fig. 5 Bottom surface microstructures of the splat with respect to the ambient pressure and substrate temperature change. (a) Splash splat obtained on room temperature substrate at atmospheric pressure, (b) Disk splat obtained on heated to 673K substrate at atmospheric pressure or on room temperature substrate at low pressure conditions

Fig. 7 Three-dimensional transition curvature database

Fig. 8 Correspondence of the order of P_t materials with respect to the Periodic Table

By introducing the transition behavior as introduced in this section, it is obvious that thermal spray is still in the area of natural and scientific phenomenon.

NEW COATING PROCESSES BY DEPOSITION OF SOLID PARTICLES

Cold Spray and Warm Spray

Materials melting in an ambient atmosphere in an ordinary thermal spray process have to be regarded as a negative

process, as it induces a chemical degradation, like oxidation or nitridation of metallic materials, and loss in an artificially designed nanostructure. It has become an essential and long-term issue in this field of technology. To overcome these problems, a coating process called CS, in which the slightly heated, softened, and accelerated solid particles deform and deposit onto the substrate surface without melting, has been developed recently.^[14,15] A typical structure of the CS system is shown in Fig. 9. Heated working gas becomes supersonic gas flow after passing through the specially designed nozzle and the accelerated feedstock powder impacts onto the substrate at high velocity and eventually results in a dense coating. Generally, there is a particle critical velocity V_c for each powder material, at which the particle collision behavior changes transitionally from an erosive collision to a deposition on the substrate surface, as shown in Fig. 10.

It is understood that, especially in the ordinary thermal spray process, the interaction between the molten particle and a solid substrate is dominated by dynamic wetting, which is accompanied by both material and thermal transfer at the interface. On the other hand, the bonding of the particle onto the substrate surface in CS can be attained by the adhesion between the highly deformed impacted particle and the slightly deformed substrate. Hence, it is estimated that the interaction between the solid particle and the solid substrate in CS may be dominated by a mechanical

Fig. 9 CS system

Fig. 10 Critical velocity V_c in CS

reaction, namely, shear instability^[16] at the sliding interface. Since the shear instability is strengthened by an increase in the velocity difference between the deformed particle and the substrate, the recent CS process is intended to increase the working gas temperature, thereby increasing both particle velocity and particle softening. On the other hand, a modified High Velocity Oxy-Fuel process has been developed in Japan, called warm spray (WS). In this process, by introducing a higher amount of nitrogen gas into the burner chamber of normal HVOF equipment, higher acceleration and optimum temperature of the sprayed particle are realized. Higher velocity and lower heating prevent the excess oxidation of the particle and result in a higher quality coating. WS is identified as an intermediate process between thermal spray and CS and is expected to be a hopeful candidate to realize higher quality coating in practical applications.

On both adhesion between the particle/substrate interface and cohesion between the interparticle boundary in CS and WS processes, the amplitude of the interfacial shear force, the rate of shear deformation, the breaking of the surface oxides, the frictional heating at interface and resultant property, and the structure degradation of the material are correlated with each other, as shown in Fig. 11. A precise bonding mechanism at the coating interface of the CS or WS, however, is still unclear and an appropriate verification is urgently desired. The South Pole problem, which was pointed out at the initial stage of the CS technology as shown in Fig. 11, namely, a residue of imperfect bonding at the collision center of the particle due to no proper material deformation, has recently been solved by experimental verification and has suggested that the impact of the following particles provides the bonding at this interface.^[17]

Aerosol Deposition Process

As an original and new particle deposition process, AD has recently been developed in Japan, by which even non-heated, room temperature ceramic powders can be coated with a high density onto the substrate surface at room temperature. The flowing behavior of powder particles

Fig. 11 Interface relating academic issues in CS and WS

with a diameter from nanometers to sub-microns in a vessel at around atmospheric pressure is called an aerosol, where powders are flowing, moving freely against gravity with ambient gas molecules, normally assisted by ultrasonic vibration. It is almost like the smoke produced by a lit cigarette. The typical equipment setup of the AD is shown in Fig. 12. In the AD process, fine ceramic particles are accelerated by the gas flow, which is driven by the pressure difference between the inside and the outside of the chamber, and deposited onto the substrate surface. A deposition mechanism in the AD process is defined as a shock consolidation at room temperature.^[18] It is more adoptable to brittle ceramic material rather than ductile metallic materials.

The shock consolidation at room temperature is a deposition mechanism of AD, explained by when collided ceramic powder breaks into several pieces during the impact on the substrate surface, the newly appeared fresh surface of the powder makes re-bonding possible between the interpieces or at the powder/substrate interface, and the resulting adhesion brings about the formation of a highly bonded dense coating. The observation result reveals that the grain size of the coating is smaller than that of the feedstock powder and supports the reliability of the above hypothesis. However, a direct observation result, showing the existence of the re-bonding interface structure after breaking the powder into small pieces, has not been reported up to now. Moreover, it is still unknown whether all of the collided and broken powder pieces adhere completely or partially onto the substrate surface. Adhesion behavior in AD has to be clarified more precisely in any future study. Practically, it has been pointed out that an optimum powder size and critical powder

Fig. 12 AD system

velocity, which enables more effective coating formation, may exist in AD, and thus, the process can be controlled more effectively by such critical process conditions.^[18]

Ceramic Coating Formation by Cold Spray

Since the plastic deformability of the powder material becomes a premise for the coating formation in CS in general, the process is inapplicable for the brittle ceramic materials as a principle. However, a possibility of ceramic coating formation was experimentally revealed recently in a kind of ceramic powder. Figure 13 shows an overview and a cross-sectional microstructure of the coating. A dense TiO_2 coating with $150\mu\text{m}$ thickness was fabricated. The key to understanding the deposition in this case is the powder structure. The microstructure of the powder was therefore precisely investigated. As a result, it was found that a few nanometer-sized primary particles are agglomerated with each other, and the resultant secondary powder has an average diameter around $20\mu\text{m}$. It is indicated that an agglomeration of nanometer-sized primary particles into $20\mu\text{m}$ size secondary powder makes it possible to feed the powder with the carrier gas and enables the fine particles to pass through the shock wave to reach onto the substrate surface for making the coating. Compared with AD process, it is inferred that the high-quality thick coating, deposited with CS, was fabricated by a collision and breaking up of the secondary agglomerated particles onto the substrate surface. Fabricated TiO_2 coating contains 100% anatase phase, and the NO_x reduction property is more superior to the feedstock powder material.^[19,20] It is considered from the result that the similar agglomerated structure of nanometer-sized primary particles may give a wide scope for the formation of high-quality ceramic coating by the CS process.

SUMMARY

On the ordinary thermal spray process, as a representative of a thick coating formation process, a process controlling principle was introduced by the three-dimensional transition curvature discussed in the flattening behavior of a single splat. On the other hand, based on the fact that the material melting is a kind of negative process, the new processes characterized as a coating process by the non-melted solid particles, such as CS, WS, and AD, were introduced. Further investigation on the deposition and flattening behavior of a single particle on a substrate surface is strongly desired to verify the deposition mechanism between a solid particle and a solid substrate and to establish the controlling principle of the process.

These new non-melting particle deposition processes may open up and realize new coating possibilities, especially on the many kinds of artificially designed nanostructured coatings, ultra-thick bulky structure formation, sublimation ceramic coating, and so on. Generally, these are recognized as impossible materials for the ordinary thermal spraying method. In the near future, a comprehensive approach to establish both an academic and a technological foundation is earnestly desired to combine thermal spray, WS, CS, and AD, which are characterized as the particle deposition process.

Abstract

This article presents the brief overview of fairly recent and eco-friendly micro arc oxidation (MAO) coating technology. The weight-cost-performance benefits in general raised the interest to utilize light-weight materials, especially the aluminum and its alloys. Despite numerous engineering advantages, the aluminum alloys themselves do not possess suitable tribology and corrosion resistance. Therefore, improvements in surface properties are essential to enable developing potential industrial applications. For improving wear and corrosion resistance of Al alloys, the most demanding surface properties are high hardness and chemical inertness. The technical and technological limitations associated with traditional anodizing and hard anodizing processes have been the strongest driving force behind the development of new MAO technology. While presenting the key technological elements associated with the MAO process, the basic mechanism of coating formation and its phase gradient nature is presented. Influence of various process parameters including the electrolyte composition has been discussed. The typical microstructural features and distribution of α - and γ - Al_2O_3 phases across the coating thickness as a key strategy to form dense coatings with required mechanical, tribological, and corrosion properties which are vital to meet potential application demands are briefly illustrated.

Keywords: Alumina; Ceramic; Composite; Fatigue; MAO; Microarc oxidation; Plasma anodizing; Plasma electrolytic oxidation; PEO; Tribology.

INTRODUCTION

In the era of persistent quest for lighter, more durable, energy efficient and recyclable materials, need to replace many previously employed materials (such as steels and cast irons) that were not in the aforementioned property framework, the utility of aluminum and its alloys has gained momentum due to their relatively higher specific strength (strength-to-weight ratio), excellent castability and formability. However, relatively poor surface hardness of aluminum alloys leading to adversely reduced component life cycle, especially under tribological contacts due to wear, friction, and corrosion damages, limits their application spectrum. Further, while most materials are expected to deliver multifunctional properties and performances, often the available material's choice window is quite narrower than one can normally visualize and therefore becomes almost mandatory to opt for nonconventional material processing routes such as surface coatings.

In the aforementioned context, there exist a few popular coating techniques employed to enhance surface hardness of aluminum alloys such as anodizing, hard anodizing,

hard chrome plating, etc. The use of fairly stronger acidic processing environment for promoting in situ oxidation has been the primary limitation in the age of growing concerns about environmental protection.^[1-2] In addition, the demand for higher surface hardness and reduced porosity over and above than what the above techniques could offer has driven the development of an eco-friendly micro arc oxidation (MAO) coating process. The MAO process is also very popularly known as plasma electrolytic oxidation (PEO) process, wherein high-voltage multiple surface discharges are created on the aluminum component surface in an alkaline electrolyte medium such that the resultant ceramic coatings are denser and harder (up to 2000 HV).^[3] It is also appropriate to note that mechanism of coating formation is quite different than that of traditional anodizing process, which is dealt in greater detail in the following sections. The MAO coatings were already recognized as a successful replacement option to conventional anodizing and hard anodizing techniques, wherein the wear and corrosion is of primary concern. It is also interesting to note that many steel components could be reengineered with aluminum as the MAO coating technology is already

matured into the industry scale of operations. There exist several global groups concurrently working on this exciting technology such that the potential benefits of MAO coatings could be extended to numerous fields of engineering. The salient outcome of all such efforts in the present context is summarized and briefly presented in this article.

BACKGROUND

The protection of aluminum alloys from wear by applying a topcoat of ceramic material is currently of great interest. Formation of ceramic topcoat on Al components is accomplishable in many different ways such as anodizing, thermal spraying, sol-gel, etc. However, as traditionally known for decades, the electrochemical oxidation technique known as anodizing has been the primary process to form protective oxide layers on aluminum components.^[4] The Al part to be treated is connected to positive terminal of a direct current (DC) power supply (anode), while nonreactive materials such as stainless steel and lead connected to negative terminal (cathode) are immersed in low pH (acidic) aqueous electrolytes containing chromic acid, orthophosphoric acid, sulfuric acid, oxalic acid, or combination thereof. The typical voltage applied is in the range of 20–50 V.^[5] The nucleation-driven hexagonal array of pores formed on the component surface grows perpendicular to the component surface to translate the diffused oxygen from the electrolyte and its reaction with the underlying Al into the coating formation predominantly at the substrate-coating interface.^[6] Therefore, the first formed coating oxide continues to remain as coating top surface irrespective of treatment time and coating thickness.

While the anodized layer is generally porous with well-distributed pores extended perpendicular to the coating surface, the dense barrier layer at the pore bottom is responsible to provide adequate resistance to the passage of corrosion medium through it. However, it may be noted

that the relative thickness of the barrier layer as compared to the anodic coating is much lesser and therefore has a limit on the overall corrosion protection. In addition, although hydrothermal sealing of anodic layer is generally employed to seal the pores such that the corrosion resistance is significantly improved, the wear resistance is still limited by the relatively low hardness of the coating. The modified conventional anodizing process, termed as “hard anodizing” or “type III anodizing,” utilizes increased acidic concentration of the bath, reduced bath temperature to subzero levels, increased process voltages, and permits the deposition of much harder oxide layer with improved coating thickness.^[7] However, the basic limitations such as its inability to effectively treat “Al–Si” and “Al–Cu” alloys (used in most automotive and aerospace applications) with relatively higher Si or Cu alloying concentration could not be addressed. The hard anodized coating with hardness values in the range of 400–500 HV although provides good scratch resistance; the wear resistance under external abrasive particle influence is quite limited. Besides such a limitation with respect to achievable coating properties, both anodizing and hard anodizing seriously suffer from the acidic contamination of the surrounding environment.

Primarily driven by the multidirectional limitations of conventional anodizing and hard anodizing processes, the development of new technology called MAO has shaped up. Although micro arcing phenomenon was initially observed by scientists few decades ago; further research investigations during the last one and half decade have laid a stronger foundation for the MAO technology. Although it was believed that the MAO process was initially meant for military purposes, it is now being widely acknowledged as a fascinating technology attracting an increasing attention from academia, research, and industry.^[3] For example, Fig. 1 illustrates that the number of science citation index (SCI) journal articles published between the years 2000 and 2014 clearly highlights significantly increasing articles published year after year and therefore the cumulative number

Fig. 1 Number of articles related to MAO coatings published in SCI journals between the years 2000 and 2014

of articles. Such a huge scientific contribution in terms of consistently increased number of articles was possible by the contributions of increasing number of academic institutions, research labs, and the industries located all over the globe engaged in the MAO technology research and practice.

As mentioned before, the MAO also popularly known as PEO, spark anodizing, and micro discharge oxidation involves surface oxidation under the action of high voltage in an alkaline electrolyte medium and ensures the formation of crystalline, dense, and protective oxide film on the aluminum surface to improve corrosion and wear resistance. Most popularly, the alkaline electrolytic bath consists of water-soluble metal hydroxides and silicates.^[8] Unlike conventional anodizing, besides employing alkaline electrolyte, the MAO process also radically differs from many attributes such as (a) application of alternating current (AC) power, (b) higher voltage regime (200–600V), (c) formation of fully crystalline and dense coating, (d) electrolyte temperature close to room temperature (25°C), (e) excellent substrate-coating adhesion, and (f) ability to form composite coatings through modification of electrolyte chemistry. In addition, the ability of MAO process that is attributed to the typical coating formation mechanisms to continue coating formation even with interruptions and therefore can be used as a repair or refurbishment technology as well makes it more interesting. With such attractive characteristics, it is rather unsurprising to note that the MAO process gained global impetus as an enabling technology to provide resistance against numerous degradation mechanisms such as wear, thermal, and corrosion.

ELEMENTS OF MAO TECHNOLOGY AND PROCESS FEATURES

The MAO technology consists of three major elements: power controller, reaction chamber, and heat exchanger. Of all, the most critical element is the power controller and its characteristics. Much of the initial R&D equipment was designed to function on DC power, wherein a stainless steel reaction chamber is made as cathode and the sample to be treated is made as anode.^[9] The reaction chamber is surrounded by an external jacket through which cool water flows such that the heat generated is transferred away from the reaction chamber. In order to ensure the homogeneity of temperature and composition of electrolyte during the coating deposition period, a mechanical stirrer is provided in the reaction chamber.^[10] Such a design, although it appears very simple and more useful to carry research investigations, is limited by the size of the reaction chamber and relatively poor thermal management of the electrolyte bath. Subsequently, both laboratory and industrial scale systems were designed based on AC power, wherein the laboratory reaction chambers are usually made of transparent acrylic material so that the progress of micro arcing can be physically visualized.^[8] When

the bath size increases typically beyond 50L, especially in the case of industrial systems, a mild steel tank lined with polyvinyl chloride or fiber-reinforced plastic is used as a general practice. In both cases, the reaction chamber (tank) is insulated and electrically grounded to enhance the operational safety. Further, the substrate-coating adhesion, hardness, wear, and corrosion resistance of the MAO coatings is higher when deposited under AC pulse power mode than under simple DC or pulsed DC power modes. In the case of pulsed DC power modes, higher duty cycle and lower frequency produce harder coatings while the high frequency–low duty cycle combination results in reduced porosity, improved corrosion, and scratch resistances.^[11–13] However, owing to the shorter duration of discharges, the coatings deposited under AC bipolar pulses and high frequencies produce smooth and dense coatings with significantly reduced porosity and increased substrate-coating adhesion than those deposited under DC or low-frequency unipolar pulses.^[14] Therefore, a judicious selection of electrical power parameters is very much essential to achieve the target property combination of the resultant coating.

Nevertheless, when the AC power is employed, the components connected to all the electrode terminals are coated simultaneously and therefore the electrical power is better utilized. Further, in the advanced systems, the electrolyte is made to circulate continuously through an external heat exchanger such that the overall thermal management is accomplished in a better manner. In the case of continuously circulated systems, the compositional and thermal homogeneity of electrolyte is achieved by means of adjustable flow controllers and also by placing an external electrolyte reservoir between the reaction chamber and heat exchanger. More details about such design features and respective advantages were discussed elsewhere.^[8]

In the case of AC power controllers employed for MAO coating deposition, pure sinusoidal waveform is sparingly used while pulsed waveforms are popular and known to deposit dense coatings. Both voltage and current pulses are shaped such that the anodic and cathodic pulses can be independently controlled. The shape and relative magnitude of anodic and cathodic pulses are designed such that oxidation reactions are driven more vigorously during anodic pulse (10 ms for 50Hz frequency) while cathodic pulse is more responsible for densification of the coating by means of sintering or sealing effect.^[8,15] A three-phase power controller is advantageous in terms of equal electrical load distribution on different phases of power supply transformer. Such equal phase loading is possible if all the three phases are balanced by means of connecting identical surface area to be coated per phase. Therefore, in the case of three-phase system, the components to be coated should be in the number equal to the multiples of 3. In view of the above, although simplified single-phase AC systems are also used for carrying out research studies, three-phase systems are popularly used for all industrial scale operations to handle large area coating requirements. Industrially,

although the MAO coating deposition is accomplished in batch production mode, continuous coating deposition on thin foils and wires, wherein length is in excess of several hundreds of meters, was also demonstrated.^[15]

Typical MAO processing constitutes continuously circulated electrolyte maintained at 20°C–30°C with the help of an external heat exchanger. The samples to be coated are immersed in the electrolyte, and the specially regulated power is supplied to achieve the coating deposition as shown in Fig. 2a while the multiple components simultaneously being coated in a reaction chamber are shown in Fig. 2b. The coating deposition is generally carried out at a constant current density of 0.1–0.3 A/cm². The most important and critical aspect of MAO coating deposition is the varying voltages as the coating thickness increases. In order to promote the electrical breakdown of the coating formed and enable the plasma-driven oxidation reactions, the increase in voltage becomes essential to compensate the increase in coating resistance as the coating grows thicker. Therefore, the typical secondary voltage window of the transformer is designed between 0 and 600 V. Utilizing such a voltage window, it is possible to achieve a coating thickness up to 100–150 μm on most Al alloys. It is also noteworthy to mention that the thin naturally formed oxide layer present on

the surface of Al alloys need to be removed thoroughly for preparing the substrate for anodizing while such oxide layer (need not be removed in the MAO process) acts as a building block for achieving quick passivation in the MAO process such that the potential buildup attains the current–voltage (*I–V*) window required for micro arcing regime. After the coating deposition, the coated components are taken out of bath and rinsed in running water, and then dried in hot air. Depending upon the functional usage, the option to grind, lap, or polish the coating surface is resorted to meet the surface finish requirements of industrial components.

MECHANISM OF COATING FORMATION

As mentioned before, the mechanism of MAO coating formation is quite different in numerous aspects. There exists a vast published literature that either directly or indirectly deals with the MAO coating formation mechanism. Considering the complex nature of the mechanisms proposed as well as the fact that the process parameters employed for coating deposition also influence the coating formation, this article presents only the generalized view point. Accordingly, the moment aluminum substrate surface is exposed to highly oxidizing electrolyte comprising metal hydroxides and silicates, the thickness of naturally formed oxide film grows by itself and thus the surface gets passivated. Presence of such passivated film increases the resistance to subsequent passage of electric current and therefore the sample to be coated acts as a resistor. Upon supplying pulsed high voltage power, nearly at about 125–150 V, the electrical breakdown of the existing oxide film occurs and results in micro arcing phenomenon. Each breakdown channel physically connects the underlying substrate with the surrounding electrolyte, outward ejection of aluminum ions, and inward flux of oxygen ions forms a plasma column as schematically illustrated in Fig. 3a, results in formation of molten alumina. Due to prevailing high temperature (of the order of 3000°C) and high pressure within the plasma column, the molten reaction products (oxides) are ejected out representing a miniaturized volcanic eruption.^[16] Owing to the strong electric field around the sample surface, the molten reaction products get deposited on the previously solidified coating surface and undergo rapid solidification. Such a rapid solidification as promoted by the surrounding electrolyte at the room temperature results in the formation of metastable γ -Al₂O₃ on the coating surface. As the channel gets cooled, the molten oxide within the channel also gets cooled as shown in Fig. 3b. Due to rapid solidification, the molten oxide forms circular ring like pancake structure on the coating surface as shown in Fig. 3c. It is preferred to have flat pancake structure with diameters much larger than their thickness (as shown in Fig. 3d) as it would be easy for the adjacent pancake to bridge the height of the previously solidified pancake. In other words, if the solidified top surface appearance

Fig. 2 (a) Schematic illustration of MAO coating process with a three-phase AC power supply and (b) multiple components connected to different phases being simultaneously coated

Fig. 3 Schematic illustration of mechanism of coating formation in which (a) discharge channel ejecting out the molten alumina and (b) solidified alumina in the discharge channel and on the coating surface forming (c) typical pancake coating surface morphology (d) eventually resulting in dense coating microstructure

resembles more hills and valleys due to parabolic pancakes with upward projection, rapid solidification does not allow the perfect bridging of its walls with the adjoining pancakes and therefore the coating eventually appears more porous. Since these pores are isolated, the overall corrosion protection may not be at stake while the wear resistance is seriously impaired. Therefore, depositing a dense coating through flatter pancakes is vital for diverse industrial applications demanding high wear resistance.

The series of breakdown events as can be visualized in the form of micro arcs with a typical population density of 10^0 – 10^{16} per m^2 on the sample surface moves chaotically all over the area such that the resultant coatings are uniformly thick. This phenomenon can be readily visualized in the form of component surface glow due to visible arcing. With this explanation, it is also clear that the freshly formed coating is always at the coating surface while the interior of the coating gets structurally refined due to the thermal energy transferred from the walls of the active breakdown channels. It is well known that metastable $\gamma\text{-Al}_2\text{O}_3$ is transformed into the more stable $\alpha\text{-Al}_2\text{O}_3$, especially when the former is heated to a high temperature in the range of 800°C – 1000°C .^[17] Therefore, it is now understandable that the interior of the coating will have more $\alpha\text{-Al}_2\text{O}_3$ than the coating surface. Since the region of the coating close to the substrate-coating interface undergoes repeated cycles of heating and cooling due to continuously erupting discharge channels, it is expected that the

amount of $\alpha\text{-Al}_2\text{O}_3$ is highest close to the substrate-coating interface and its proportion gradually decreases toward the coating surface as shown in Fig. 4a.^[18] Such a phase compositional variation across the coating thickness not only makes the coating a uniquely graded composite but also results in corresponding variation in hardness across the coating thickness as shown in Fig. 4b. In view of this mechanism and associated phase transformation, the thicker MAO coating always exhibits higher peak hardness (close to the substrate coating interface, marked as “P” in Fig. 4b) value than a thinner coating as shown in Fig. 4c is quite appreciable.^[16] In addition, since $\alpha\text{-Al}_2\text{O}_3$ is a thermodynamically stable, much harder, and stronger phase than $\gamma\text{-Al}_2\text{O}_3$, increased relative proportion of the former phase is always advantageous. Therefore, MAO coating technology allows the tailoring of coating hardness simply based on final coating thickness suitable for diverse application requirements.

INFLUENCE OF PROCESS VARIABLES

As discussed before, the electrical power source characteristics are vital for depositing dense, hard coatings with good substrate-coating adhesion. In addition, the following process parameters influence the overall coating morphology and its composition, which is also vital for judging the overall coating quality.

Fig. 4 (a) Typical distribution of α -Al₂O₃ and γ -Al₂O₃ phases, (b) corresponding hardness gradient across a 100 μ m thick MAO coating deposited on 6061-T6 Al alloy, and (c) variation in peak hardness as a function of final coating thickness

Electrolyte Composition

Electrolytes are typically composed of silicates, aluminates, metaphosphates, borates, and hydroxides with additives such as vanadates, permanganates, polymers, and dispersants. Such soluble/insoluble additives are added to the distilled/demineralized water in specified optimum proportion to prepare the electrolyte. Optimization of relative concentrations of the above constituents in the electrolyte is the key to deposit uniform coatings. Although many electrolyte additives are attempted, most commonly used electrolyte composition comprises of potassium hydroxide and sodium silicate. Experimental investigations have revealed that the addition of sodium silicate proportion more than that of potassium hydroxide leads to deposition of more thicker coating especially at sharp edges. While this scenario is advantageous in few applications where strengthening of thinner sections/edges is required, in general sodium silicate

concentration is kept at approximately half the level of potassium hydroxide content. Accordingly, 3–5 g/L of KOH and 1.5–2.5 g/L of Na₂SiO₃ per liter of distilled/demineralized water is commonly employed for achieving homogeneously dense, uniform coating on a wide variety of Al alloys.^[19]

Electrolyte Temperature

Unlike hard anodizing in which the electrolyte needs to be cooled to subzero Celsius temperature, the electrolyte in the MAO process is maintained at room temperature. Approximately, about 30% of the electrical power fed to the samples (components) is converted into heat energy during the electrical breakdown-assisted plasma-driven MAO coating deposition process. Therefore, the electrolyte temperature, unless continuously cooled, increases rapidly especially at higher current densities. Therefore, heat exchanger is most commonly employed to maintain constant electrolyte temperature (as a recommended practice) during the entire coating deposition time. Although, the increase in temperature up to 40°C appears to marginally reduce the coating deposition rate, isothermal evaporation rate of water from the electrolyte becomes more significant beyond 40°C.^[19] Since higher evaporation rate leads to inhomogeneous bath composition, which in turn degrades the coating quality during longer hours of operation, periodic replenishment of electrolyte is essential.

Current Density

Usually, the MAO process kinetics is better controlled under constant current density mode, occasionally constant voltage mode is also employed. Under constant current density mode, the current to be supplied is calculated based on the surface area to be coated in such a way that the current density is maintained between 0.1 and 0.3 A/cm² while current density greater than 0.4 A/cm² tends to shatter the coating due to excessive, uncontrollable sparking. Increasing current density from 0.1 to 0.3 A/cm² concurrently increases the coating deposition rate by the same order of magnitude (about three times more). For instance, under identical processing conditions, 6061 T6 Al alloy under AC pulse power mode typically exhibits 0.6–0.65 μ m/min coating deposition rate at 0.1 A/cm² current density while exhibits about 1.8–2.0 μ m/min at a current density of 0.3 A/cm².^[20] Yet, another interesting feature of MAO process is its linear kinetic deposition rate. Usually, the diffusion-controlled coating deposition processes do not exhibit linear variation in coating thickness with respect to processing time as in the case with conventional anodizing. However, in the case of MAO process, many researchers have experienced linear coating deposition kinetics, especially when the coating thickness is less than 100 μ m.^[20,21] Due to such linear kinetics as shown in Fig. 5, once the average coating deposition rate is calculated, it is easier to calculate the oxidation time required to deposit a given coating thickness.

Fig. 5 Progressive coating thickness with MAO treatment time indicating linear coating deposition kinetics and slope of the straight line fit gives the average coating deposition rate per minute (1.99 $\mu\text{m}/\text{min}$) for 6061-T6 Al alloy at 0.3 A/cm^2 current density

Interelectrode Distance

Under the DC mode, the stainless steel tank is made a cathode, the sample to be coated (anode) is placed usually at the geometrical center of the tank. Therefore, the interelectrode distance varies with varying sample geometry for a given tank size and shape. In other words, for rectangular tank geometry, irrespective of the sample location, the distance between sample surface and the nearest tank wall changes significantly. Such a scenario can lead to deposition of varied coating thickness on different faces of the component. In addition, the relative ratio of surface areas of cathode to anode becomes another process variable to be properly optimized to achieve quality coatings. However, when AC power is employed, the interelectrode distance means the distance between the samples connected to different phases rather than the distance between the samples connected to the same phase. Further, since anode and cathode role switches between the samples themselves during each half cycle of current and voltage pulses of AC power, the relative cathode to anode area has no meaning and therefore the interelectrode distance can be maintained uniformly, especially in the case of samples with regular geometry. In view of the above, the possibility of depositing uniformly thick coating on all sides of the sample is more in the case of AC power mode. However, the sample rotation in the case of large area components with irregular geometry is recommended to achieve the uniform coating. An increase in interelectrode distance from 60 mm to 120 mm does not appreciably change the coating thickness on 7075 Al alloy indicates that a reasonably larger window of interelectrode distance is available during the MAO coating deposition under AC power mode.^[19]

INFLUENCE OF ALUMINUM ALLOY SUBSTRATE COMPOSITION

As mentioned earlier, electrolyte additives play a significant role in modifying the coating morphology and its

composition. Similarly, the alloying elements present in Al alloy changes the coating morphology and phase composition. Due to the typical mechanism of MAO coating formation as explained before, the coating grows both inward (into the substrate) and outward (above the original mean surface level). Such a growth is accompanied by simultaneous substrate melting at the base of discharge channel and therefore enables the alloying elements to take part in the coating formation process. Since most common alloying elements such as Cu and Zn do not readily form respective oxides, in the coating their role in promoting a particular phase formation is rather unclear as their relative percentages added to Al alloy were generally low. However, in the case of Al–Si alloys, silicon is added in substantially higher quantities (6%–13%), the profound effect is clearly noticeable.^[20] Increasing “Si” content of Al–Si substrate increases the formation of Al–Si–O (mullite) phase and also makes the coating relatively porous.^[22] With isolated pores distributed in the coating, the mullite-bearing coating exhibits better heat shielding capability and substantially reduced coefficient of friction even under dry sliding wear mode than the coatings deposited on non-“Al–Si” category alloys. Other important alloying elements added to Al alloys such as Mg and Li appear to take active part in the oxidation process and therefore the average coating formation rate on Al–Mg and Al–Li alloys is significantly higher than the Cu-, Zn-, and Si-bearing Al alloys.^[20] Nevertheless, one most common influence of any alloying element has been on the kinetic coating deposition. The typical coating formation rate at 0.3 A/cm^2 current density ranges from 1.4 to 2.0 $\mu\text{m}/\text{min}$ is depending upon the type of alloying element and its relative quantity. Depending upon the substrate composition, the MAO coatings deposited on different Al alloys typically exhibit the peak hardness in the range of 1200–1900 HV when they were grown to an identical thickness of about 90–100 μm as shown in Fig. 6a while the corresponding wear rate under abrasive and sliding wear modes as significantly influenced by the substrate composition is clear from Fig. 6b–c, respectively.^[20] Further, the coatings formed on commercial pure and 6xxx series Al alloys in general appear as milky to creamy white in color while the coated 7xxx and 2xxx series alloys appear to exhibit light to dark brownish color, respectively. Such a notable difference in the color contrast of MAO-coated Al alloys is as a result of interaction and incorporation of different alloying elements to a varying degree during the coating formation. For example, in the case of MAO treatment of 2214 Al alloy, the copper-rich intermetallic phases induce the incorporation of copper nanoparticles in the $\gamma\text{-Al}_2\text{O}_3$ layer and contribute to not only the color contrast but also the varied reaction kinetics, and therefore influence the coating deposition rate as well.^[23]

Fig. 6 Influence of substrate composition on (a) peak hardness, (b) abrasive wear rate, and (c) sliding wear rate of MAO coatings deposited on 10-different Al-based substrate materials

TRIBOLOGICAL PERFORMANCE

It is also noteworthy to mention that the hardness of thicker MAO coating is significantly higher than the thinner coating as illustrated in Fig. 4c. The typical mechanism of coating formation associated with $\gamma\text{-Al}_2\text{O}_3$ – $\alpha\text{-Al}_2\text{O}_3$ transformation as discussed previously is the reason behind such an unusual phenomenon. With such a high hardness, the ceramic coatings as deposited through MAO technology are expected to perform better under diverse wear modes. The abrasive wear rate of MAO coatings as compared to the hard anodized coatings deposited on 6061-T6 Al alloy with angular SiO_2 as abrasive medium is about 12 times lower as shown in Fig. 7a. In addition, under rubber wheel abrasion conditions, the MAO coatings offer exceptionally better wear resistance even under high stress conditions as

Fig. 7 Abrasive wear behavior of $55 \pm 2.5 \mu\text{m}$ thick MAO coatings deposited on 6061-T6 Al alloy in comparison with the bare (uncoated) substrate and identically thick hard anodized coating (a) as a function of abrasive wheel rotations at 10N normal load, (b) as a function of applied load (1–50N), and (c) as a function of abrasive wheel rotations at 50N normal load

shown in Fig. 7b. The ability to withstand up to 1500 abrasive wheel rotations at 50N normal load by when the MAO coating is almost completely removed as shown in Fig. 7c while the hard anodized coating is completely removed within first 10 abrasive wheel revolutions clearly highlights the superior wear resistance of MAO coatings.^[24] Further, the MAO coatings are also found to perform significantly better under other wear modes such as dry sliding, lubricated sliding, fretting, and erosion. More importantly, the wear resistance of MAO coatings is found to be marginally better than the well-established thermal spray Al_2O_3 coatings deposited on 7075-T6 Al alloy by detonation spraying coating (DSC) technique as shown in Fig. 8.^[24]

Fig. 8 Comparative abrasive wear performance of MAO coating with identically thick ($\sim 100 \mu\text{m}$) most competing alumina coating deposited on 7075 Al alloy through DSC in comparison with bulk sintered alumina at 50 N normal load

Yet another interesting observation is the significant ability of MAO coatings to offer continuously decreased wear rate as the material removal progresses. With typical hardness gradient as shown in Fig. 4b due to the increased proportion of $\alpha\text{-Al}_2\text{O}_3$ content as shown in Fig. 4a, the deeper regions of the coating resisting the material removal more elegantly than the surface regions of the coating is clearly understandable.^[18] Therefore, when a 90–100 μm thick MAO coating is subjected to dry sliding wear test, as the material removal progresses and deeper regions of the coating are exposed to “WC-Co” sintered disc, the material transfer from the disc to the coating leading to the formation of harder and brittle mechanically mixed layer (MML) is evident as shown in Fig. 9.^[18] The tribological test results presented by numerous independent researchers across the globe clearly confirms the superior load bearing capacity of MAO coatings resulting in exceptionally improved wear performance of Al alloys. Therefore, the consideration of MAO coatings as a potential tribological solution for many industrial components that are prone to wear degradation during their service life is understandable.

CORROSION PROTECTION

In general, the MAO coatings are free from interconnected porosity. Owing to its typical coating formation mechanism, the discharge channels also get filled with solidified alumina thereby leaving a shrinkage cavity on the coating surface. While such shrinkage cavities present on the coating surface get filled with molten alumina during subsequent discharge events, the topmost layer is expected to exhibit such cavities leading to increased surface roughness with increased coating thickness.^[16] Under such a scenario, the finer nanoscale porosity present in the bulk of the coating being isolated does not provide easy access to corrosion medium to react with the underlying substrate.^[17] In contrast, the conventional anodized coatings exhibit pores that almost connect the coating surface with the underlying substrate except with a relative thin and dense barrier layer at the substrate-coating interface.

In view of the two distinctly different coating formation mechanisms as explained previously, the MAO coatings are much denser and therefore expected to protect the Al substrate in a more efficient manner than the anodized coatings.^[17,25] In line with the above argument, the potentiodynamic polarization curves pertaining to bare 6061-Al substrate, hard anodized coating, and MAO coating as evaluated in 3.5wt% NaCl solution after 1 h stabilization evaluated under a three-electrode potentiostatic mode with saturated calomel reference electrode (SCE) as shown in Fig. 10 and the corresponding corrosion rates as provided in Table 1 clearly confirm the superior corrosion protection of Al alloys through MAO coatings.^[26] In the above context, it is noteworthy to mention that the corrosion current density of MAO coating is about 45 times lower corrosion current density (i_{corr}) and corresponding corrosion rate (mills per year, MPY) than the otherwise well-known corrosion-resistant material, namely stainless steel (SS-316L). Numerous studies have indicated that the corrosion protection of MAO coatings lasts longer and even after 600 h of immersion test does not make them to exhibit any visible pits.^[26] Further, since porosity present is

Fig. 9 (a–b) SEM images of worn regions under dry sliding wear mode slid against WC-Co sintered disc after 1000 m sliding distance indicating microchip-assisted MML as the predominant wear mechanism in MAO coating deposited on 6061-T6 Al alloy

Table 1 Potentiodynamic polarization test results after 1h exposure to 3.5% NaCl solution under three-electrode potentiostatic mode with SCE

	E_{corr} (mV)	i_{corr} (A/cm ² *10 ⁻⁸)	R_p^a (M Ω)	Corrosion rate (MPY)
Bare 6061 alloy	-0.8664	37.74	0.07	0.162
MAO-coated 6061 alloy	-0.7476	1.79	1.46	0.007
SS-316L	-0.291	81.5	0.032	0.334
Hard anodized 6061 alloy	-0.811	2.89	0.902	0.012

**Fig. 10** Polarization curves obtained for MAO and hard anodized coating in comparison with bare 6061 Al alloy substrate and stainless steel (SS-316L) in 3.5 wt% NaCl solution after 1 h exposure under three-electrode potentiostatic mode with SCE

of nanoscale, the corrosion product formed at the pore base near the substrate-coating interface can possibly plug the pore for a finite period of time and therefore the protection against corrosion is generally extended for longer durations.

POTENTIAL APPLICATIONS

Owing to the impressive portfolio characteristics of MAO coatings deposited on Al alloys such as superior tribological resistance, corrosion protection, thermal and electrical insulation, and high adhesion with the substrate, varied mechanical properties with a simple change in final coating thickness have attracted a great deal of industry attention to utilize this novel technology in the recent times. Most of the application conceptualization is mainly based on excellent abrasive wear resistance together with enhanced corrosion protection as offered by the MAO coatings. While the available literature is utilized to provide summary of applications in this section, the examples illustrated in this article are mainly based on the work accomplished at the authors' laboratory. The textile machine building industry has been one of the beneficiaries of this exciting technology as numerous parts that are smaller in size and larger in number, and comes in contact with yarn (mainly synthetic and also cotton based) moving at extremely high speeds and therefore demands the high abrasive wear resistance. One of the successful and earliest attempts at the authors' laboratory was to replace hardchrome-plated rollers with MAO-coated Al rollers

**Fig. 11** MAO-coated components pertaining to textile industry (a) rollers, (b) spindle pot, (c) discs, (d) guides, (e) automotive pistons, and (f) wiredrawing pulleys

as shown in Fig. 11a. The hard chrome-plated rollers were supporting the continuous production line for 4–6 months while the MAO-coated rollers have been working for about 12–15 months uninterruptedly, which highlights the greatest promise of MAO coatings. Enthused by the above outcome, numerous other textile parts such as spindle pots, discs, and guides as shown in Fig. 11b–d were also provided with MAO coatings to enhance the functional performance.

As discussed previously, utilizing the advantage of MAO technique's capability to provide coatings on cast Al–Si (non-anodizable) alloys, various automotive parts such as high-speed diesel engine pistons and fuel injection parts are being treated with MAO process. The special interest of MAO coatings on automotive engine components has been conceptualized based on two primary factors such as (a) mullite (Al–Si–O) phase formed in the MAO coating reduces the coefficient of friction significantly and (b) typical isolated porous nature of the coating formed on Al–Si alloy exhibits better heat shielding characteristics and lubricated sliding wear resistance.^[27] With such distinct characteristics, the MAO-coated pistons as shown in Fig. 11e were found to exhibit excellent thermal cycling resistance and therefore demonstrate a greater promise for its use in automotive segment.

Yet another example of industrial scenario where high wear resistance is of major concern is in the wire drawing segment. The advantage of MAO coating to offer superior wear resistance even under high stress conditions paved the path for development of these coatings on typical wire drawing pulleys as shown in Fig. 11f. The applications pertaining to various other industry segments that potentially use MAO-coated Al alloys including oil and gas (gears, valves, rotary shafts), electronic (capacitors, insulators), vacuum engineering (turbo-molecular pumps, evaporators), air and space (gears, optical devices, structural parts), crockery (pans, utensils), mobile technology (cases), and washing machine (gears, shafts) are under various stages of development across the globe.

As mentioned before, the ability of MAO technology to provide coatings with varied compositions and phases on a wide variety of not only Al alloys but also on the metals and alloys of Ti, Mg, Ta, and Zr, considerable work is in progress to explore the possibility of utilizing the coated components in a wide variety of fields including biomedical, photo catalysis, and solar and nuclear energy segments.^[28–30] In view of the primary scope of this article to limit to Al alloys, the progress made in terms of both research and potential applications of MAO coatings deposited on other than Al alloys has not been discussed in this article.

CURRENT TRENDS AND CHALLENGES AHEAD

With an objective to achieve the functional performance and also to further enhance the property portfolio of MAO coatings, multidirectional research tasks have been

carried out in the recent times. Two major such directions encompass (a) incorporation of novel additives to the conventional alkali silicate electrolyte and (b) formation of duplex coatings by combining the MAO coating with radically different coating technologies. The efficiency of insoluble additives such as graphite particles, rutile TiO_2 particles, and nano- Al_2O_3 particles was investigated.^[31–33] These additives were found to be effective in changing the morphology, composition, deposition rate, and resulting tribological performance of MAO coatings. Further, addition of $\text{Ce}(\text{SO}_4)_2$ and $\text{La}(\text{NO}_3)_3$ was found to effectively reduce the corrosion rate and coefficient of friction while the addition of later compound is relatively more effective than the former additive.^[34] The overall outcome of such studies is expected to result in improving the process economics by way of reducing the overall cost of the coating while the promise to deliver the functional properties of industrial applications is enhanced further.

In a direction to achieve multifunctional performance as stated above, duplex coatings are also being attempted. The sol–gel coatings, when applied on the top of MAO coating, are expected to seal the pores present in the topmost MAO layer thereby the corrosion resistance is significantly improved.^[35] Of the sol options among cerium nitrate, potassium dichromate, and silica, the silica-based sol–gel coating exhibits a better sealing effect and therefore serves as better barrier layer against corrosion attack than the other two options.^[36] The diamond-like carbon film deposited by plasma immersion ion implantation technique as a topcoat on MAO coating appears to reduce the coefficient of friction and improves the overall tribological performance.^[37]

Enhancing or at least retaining the fatigue resistance of Al alloys even after the MAO coating is of prime interest to the aerospace industry. Although the MAO coating in general degrades the fatigue life of Al alloys due to the tensile residual stress state at the substrate-coating interface, the extent of fatigue degradation is much more severe in the case of hard anodized Al alloys.^[38] Reduction in endurance limit by 5%–10% and 75% by the MAO and hard anodized coatings, respectively, as compared to the corresponding bare Al alloy substrate (6061-T6) clearly highlights the aforementioned phenomenon.^[39] Therefore, as it is traditionally well known that the introduction of compressive residual stresses significantly retards the fatigue crack propagation rate,^[40–41] shot peening prior to the MAO coating deposition appears to be a promising solution for avoiding the fatigue degradation.^[42] In addition, impregnation of epoxy resin on to the MAO coating surface not only fills the micropores or micro-pits but also welds the original thermal cracks, thereby the crack initiation and early stage crack propagation resistances are synergistically improved.^[43] Although the aforementioned results illustrate the potential of MAO coatings to offer extended fatigue life, more coherent work is necessary in this direction such that the MAO coatings can be successfully realized as an industrial solution.

With the advent of MAO technology, towards the objective of overall weight saving, wherever the bulk strength is not a matter of concern, the components previously made out of steel and cast iron are now being attempted to manufacture with Al and provide the MAO coating to protect the component from wear and corrosion damage in various industrial environments. Although this concept is currently being extended to few areas, much more work is required to realize many industrial applications in this direction. Since the electrical power is regarded as one primary attribute significantly adding to the overall cost of the coating, the efforts to realize the process parameters including the electrolyte additives resulting in notable reduction in overall energy consumption per unit thickness of the coating are of certain interest to the industry. Such efforts will bridge the economic gap between the industry cost tolerance levels and actual MAO coating cost and therefore the application basket is expected to get widened. While doing so, in spite of MAO technology regarded as eco-friendly, concurrent reduction in average power consumption per unit thickness of the coating makes it more greener technology. Utilizing the recent developments in the field of process diagnostic tools, the new generation intelligent MAO process controllers can be developed not only to derive superior understanding about the MAO process but also helps in automating the MAO process suitable for large-scale operations.^[44]

It is also pertinent to mention that the MAO coatings have the potential to replace numerous textile and other industry parts that are currently made out of solid alumina ceramic material to ultimately utilize the advantages in favor such as (a) reduction in overall component weight such that the parts become friction driven and therefore energy consumption is significantly reduced, and (b) easy to drill holes, prepare and shape edges and corners either before the Al alloy is coated or after the coating which would otherwise not easily possible while working with solid ceramic parts. It is also apt to mention that there is a need to develop the nonconventional grinding and polishing methods such that the MAO-coated parts will readily fit into the applications demanding high-quality surface finish. Such efforts are essentially required because the coating is harder and thus makes the surface finishing line more demanding. Last but not least, concentric efforts are needed from all spheres including academic, research, and industry counterparts such that the potential benefits of exciting MAO technology can be fully realized and the overall benefit of component life cycle enhancement is meritoriously extended to various industry segments.

CONCLUDING REMARKS

The DC-based power controllers in general are used for accomplishing research investigations while the three-phase AC power controllers are quite useful to design

industry-scale systems. Of all the MAO process parameters, the electrolyte composition and current density influences the coating deposition rate, morphology, composition, tribological and corrosion resistance. Owing to the radically different formation mechanism of MAO coating and therefore the resultant dense and gradient coatings with α -Al₂O₃ and γ -Al₂O₃ phase distribution, the overall tribological properties under diverse wear modes and the corrosion resistance are exceptionally good. Many industrial segments such as textile, automotive, aerospace, oil and gas, vacuum engineering, wire drawing, etc., are expected to get greatly benefited by the MAO technology. More focused R&D investigations in a synergistic manner are required to improve the fatigue performance of MAO-coated Al alloys over and above the corresponding bare Al alloy substrate to expand the aerospace application spectrum. Enhancing the coating deposition rate through electrolyte additives and reducing the overall energy consumption of MAO coating per unit thickness without any compromise on the coating quality will be the envisaged direction to attract broader industrial application spectrum.

Corrosion Inhibitors: Effect on Aluminum Alloys

Feyisayo Victoria Adams, Mbali Mokgatla, Abubakar Ishak, Chukwuma Valentine Onwujiuba, Pwafureino Reuel Moses, and Utseoritselaju Okorodudu

Petroleum Chemistry, American University of Nigeria, 98 Lamido Zubairu Way, Yola By-pass, Yola, Adamawa State, 640001, Nigeria

Abstract

Aluminum alloys are less corrosion resistance compared to the pure aluminum. The less corrosion resistance of the aluminum alloys results from trading their mechanical strength and stability with their corrosion resistance. Aluminum alloys show inhibition in alkaline, acidic, neutral chloride free, and chloride media. This study covers studies done on different inhibitors used in corrosion inhibition of aluminum alloys in various media. Generally, the inhibition efficiency of the inhibitors increases with increase in the concentration of the inhibitors. The inhibition efficiency also depends on the characteristic of the inhibitor; whether it is a mixed-type, anodic, or cathodic inhibitor. The experimental data fit in Langmuir adsorption isotherm indicates physical adsorption, while Gibb's free energy values show that aluminum alloys' corrosion inhibition is by spontaneous adsorption process. The addition of chloride in alkaline solution improves corrosion inhibition of aluminum alloys.

Keywords: Acid; Alkaline; Chloride; Environmentally friendly; Inorganic; Organic.

INTRODUCTION

Aluminum is commonly used in automobiles, aircraft, cans and foils for packaging, construction, electricity, and even some consumer products such as cooking utensils.^[1] Some elements such as zinc, manganese, nickel, magnesium, copper, chromium, and silicon are added to the pure aluminum to increase its strength to make it easy for it to be machined. This process is known as alloying. Aluminum alloying depends on the desired applications, as it is naturally not a strong metal. Aluminum alloys include magnalium, duralumin, and alnico.^[2] Magnalium is composed of aluminum and a small quantity of magnesium and nickel. Magnalium is used in the production of scientific instruments and metal mirrors. Duralumin consists of small amounts of magnesium, manganese, and copper added to pure aluminum. This aluminum alloy is highly used in aircraft construction. However, copper may strengthen duralumin, but it serves as a good medium for corrosion.^[2] A thin layer of pure aluminum called alcad is used to cover duralumin, and to protect it from corrosion by reducing its fatigue strength.^[3] Alnico is primarily composed of aluminum, nickel, and cobalt. Though it contains these elements, other elements can be added such as copper and iron. Alnico is used as a permanent magnet because of its ferromagnetic properties and coercivity.^[4] Their resistance to corrosion is stronger compared to the other aluminum alloys and coatings.

Aluminum alloys can experience corrosion fatigue leading to metal failure. Thus, additional protection is

needed to prevent corrosion and increase the life span of the alloys. For instance, it was mentioned that duralumin is vulnerable to corrosion due to the presence of copper in it.^[3] Cladding duralumin serves as an additional method of protection against corrosion. Paint can also be used to coat the surface of aluminum alloys when necessary. Temperature treatment of aluminum alloys might also be necessary according to their applications relative to the type of environment in which they are used. Other methods of protection of aluminum alloys against corrosion involve the use of the various inhibitors. Several works have been done on the corrosion inhibition of aluminum and its alloys in the different media, and a few works have been done in compiling these works as reviews.^[5-9] Uwiringiyimana et al.^[5] reported on the corrosion inhibition of stainless steel and aluminum, while Sangeetha et al.^[6] focused on the corrosion inhibition of aluminum and its alloys using green inhibitors. Khanari and Finsgar^[7,8] reviewed organic inhibition of aluminum and its alloys in chloride, alkaline, and acid media. Khanari et al. reviewed green corrosion inhibitors for aluminum and its alloys.^[9] However, this present work is directed at the effects of various corrosion inhibitors on the corrosion of aluminum alloys in various media.

CORROSION OF ALUMINUM ALLOYS

The aluminum-copper alloys (AA2xxx) have relatively poor resistance to corrosion; thus, they require surface

protection when they are to be applied in a corrosive environment such as in marine and industrial atmospheres. These aluminum alloys include 2011, 2014, 2017, 2018, 2024, 2025, 2036, 2117, 2219, etc.^[10] The salts of rare earth elements have proven to be effective corrosion inhibitors of AA2024.^[11–13] The cations in the salts form highly insoluble films on the S-phase intermetallic zones, which then prevent an increase in pH which is responsible for the acceleration of intermetallic dealloying.^[11]

Aluminum-Magnesium (Al-Mg: AA5xxx) alloys are the most corrosion resistance of all the aluminum alloys. However, their corrosion resistance depends on the method used in their fabrication. Fabrication practice has a significant influence on their long-term corrosion behavior when more than 4% Mg is used.^[14] Al-Magnesium β -phase could precipitate in the grain boundaries when the amount of Mg used is above 4%, thereby resulting in intergranular and stress corrosion in aggressive environments. AA6xxx (Al-Mg-Si) alloys give the most effective corrosion resistance when the Si percentage is not more than the needed amount to alloyed with the magnesium content to form the Al-Mg-Si alloy.^[15] However, their corrosion resistance is lower compared to the copper-free Al-Mn alloys (AA3xxx) and the Al-Mg alloys (AA5xxx). The Al-Zn-Mg-Cu alloys (7xxx) require protection in severe corrosive environments. An improper heat treatment and choice of alloy, faulty design and fabrication, and an unexpected contamination of noncorrosive environments can make the aluminum alloys susceptible to stress corrosion.

Aluminum alloys may corrode by different pathways, which include deposition, atmospheric, uniform, intergranular, galvanic, pitting, crevice, and exfoliation corrosion.^[16] Aluminum and its alloys exhibit both active and passive characteristics. This reactivity and passivity nature of aluminum and its alloys can be explained by the reaction of the alloys with oxygen or water to form a coherent surface oxide which delays further reaction of aluminum with its environment.^[17] The reactivity of aluminum, though weakness in most metals, is the key to aluminum's ability to resist corrosion. When oxygen is present in the soil, air, or water, aluminum reacts to form aluminum oxide (passive layer). This passive layer chemically adhered to the surface of the aluminum, and it seals the core aluminum from any further reaction with the environment.^[18] Equation 1 shows the reaction of aluminum with water to form aluminum oxide.

The inert nature of this stable oxide is what makes aluminum very resistant to most environments and chemical agents. It is, therefore, reasonable that the rate of corrosion of aluminum decreases with time, except in special cases, for example, when caustic soda is involved.^[19] The oxide film formed as a result of the reaction of aluminum and oxygen or water is a thin layer of about 50 Å.^[20]

Despite being thin, this layer is a strong and stable protective medium between the metal and the environment. The physical and chemical strengths and stability of this oxide are, therefore, what determine the corrosion resistance of aluminum and its alloys. The pH of the environment is one factor that largely determines the stability of the oxide film. If the environment has a pH in the range 4–9, the oxide will be stable.^[20] However, at pH ranges between 1–3 and 10–14 values, acid dissolution yields Al^{3+} ions and the alkaline dissolution results in the formation of $\text{Al}(\text{OH})_4$ ions.^[21]

In neutral solutions of non-halide salts, the protective oxide layer formed is stable. However, in halide solutions, aluminum alloys exposed to the atmosphere containing more of chloride ions can undergo pitting corrosion. This occurs as a result of the presence of oxygen, the metal being polarized to its pitting potential, and the formation of soluble chlorinated aluminum hydroxide (Eq. 2) that prevents the formation of the stable protective oxide on the surface of the aluminum alloys.^[22] In addition, alkaline substances can attack the protective oxide layer making aluminum and alloying of aluminum to reduce their corrosion resistance. Aluminum alloys experience other forms of corrosion such as intergranular corrosion and exfoliation corrosion. Aluminum and its alloys are also susceptible to galvanization corrosion. This occurs when it comes into contact with a more noble metal like graphite, with an electrolyte providing good conductivity between the metals.^[23]

CORROSION INHIBITORS

Corrosion inhibitors are organic or inorganic (anodic and cathodic) chemical substances that prevent corrosion up to 90% or more when added at low concentrations.^[24] The rate of corrosion of the metal is reduced with an increase in the polarization behavior of the anode and the cathode. It also inhibits corrosion by decreasing the movement of ions to absorb to the metal surface and increase its electrical resistance.^[24] Adsorption characteristics of organic inhibitors depend on a few factors, such as the surface charge of the metal, temperature, the chemical structure of organic inhibitors, the distribution of charge in the molecule, the type of electrolyte, the type of interaction between the organic molecules, and the metallic surface.^[25,26]

It has been reported that many organic compounds act as corrosion inhibitors, but some compounds do not possess properties such as the ability to control corrosion and be toxic, compatible, have a low cost and also be environmentally durable and friendly. Organic compounds that are corrosion inhibitors for many metals and alloys consists of

oxygen, nitrogen, sulfur atoms, and have multiple bonds.^[27] The efficiency of these compounds depends on the strength of the co-ordination bond, the stability of the formed complex and much more.

There are corrosion inhibitors (natural/plant) that have been used to control the corrosion rates of aluminum and its alloys. Plant extracts are non-toxic and environmentally stable; they are cheaper and also biodegradable.^[6] Although, scientists warn that using plant materials for corrosion inhibition could cause the plant kingdom to slowly diminish and metals will be protected at the cost of destroying the plant kingdom. The plants' extract, which has been used as inhibitors for aluminum and its alloys, includes:

An aqueous extract of *Hibiscus Sabdariffa* leaves, which serves as a good corrosion inhibitor for pure aluminum. It contains flavonoid compounds that make it capable for corrosion inhibition. A high concentration of the inhibitor increases the efficiency of aluminum alloys at lower temperatures.^[28–30] An aqueous extract of *Hibiscus Rosa-Sinensis* has high inhibition efficiency in the presence of Zn^{2+} . This inhibitor exhibits up to 98% inhibition efficiency. It acts as a cathodic inhibitor and a protective film that consists of the flower extract and Al^{3+} is formed; the film that is formed prevents the aluminum metal from corroding.^[31] Plant extract of *Hibiscus Teterifa* inhibition mechanism is based on physical adsorption. When *Hibiscus Teterifa* extract is adsorbed on the surface of aluminum and its alloys, it decreases the corrosion rate of the metal by blocking the corrosion sites on the alloy.^[6] Other organic inhibitors were reported by Sangeetha et al.^[6]

Inorganic inhibitor that has been used as inhibitors for aluminum and its alloys are Chromate conversion coatings with a concentration of 250g/L. These have been applied for many years in which Cr(III) is more suitable than hexavalent chromium Cr(VI) because Cr(III) oxide offers a barrier effect while hexavalent chromium (Cr(VI)) is carcinogenic and toxic.^[32] Different methods of corrosion inhibition have been tested, and it shows that cerium salts and salts of rare earth lanthanide are effective for inhibiting corrosion and are also environmentally stable and friendly. Salts of cerium (Ce), Ce(IV), have a low solubility; therefore, Ce(III) salts are preferable because they are more soluble in water. The type of Ce salt, its concentration, and the intermetallic particles determine the effectiveness of its corrosion inhibition. Using Ce(III) salts to inhibit the corrosion of aluminum and its alloys can be attained by precipitating cerium hydroxide salts on the cathodic sites in order to lower the oxygen reduction of the cathode; $Ce(OH)_3$ is formed due to the presence of Ce^{3+} and OH^- in aqueous solution.^[6]

Vanadate is an interesting inhibitor that researchers are keen in understanding, especially its chemistry and inhibitive properties on aluminum and its alloys.^[33–35] Vanadate, when used as aluminum inhibitor,

forms soluble vanadate that gives it an advantage over toxic chromate.^[35,36] Iannuzzi et al. validated the cathodic inhibitive effect of vanadate on AA2024 using polarization and split cell experiments.^[37] The report of the experiments showed that vanadate suppresses the oxygen reduction reaction by a physical adsorption of vanadate monolayer. Ralston et al. also reported the inhibition of vanadate on intermetallic compounds (IMCs) found on AA2024-T3 and AA7075-T6.^[38]

Corrosion Inhibition of Various Aluminum Alloys in Acidic, Alkaline, and Chloride Media

There are different ways of controlling aluminum corrosion, among different methods of corrosion control and prevention; the organic inhibitors are the most used. Organic inhibitors are used to protect aluminum and its alloys against corrosion in aggressive media because they adsorb on the metal's surface as a protective film on anodic and cathodic areas simultaneously.^[39] Most organic compounds contain polar groups such as sulfur, nitrogen, and oxygen. The inhibition of organic compounds is based on the adsorption ability of their molecules. The inhibitor molecules adhere to the surface of aluminum alloys by chemisorptions (physical adsorption) or complexation with the polar groups, which act as the reactive centers in the molecules.^[16,40,41] Aluminum alloys can be protected from corrosion by adding corrosion inhibitors which aid in decreasing the rate of corrosion. The efficiency of the corrosion inhibitors is directly proportional to the concentration of the inhibitor but inversely proportional to the temperature.^[42,43]

Ananas sativum (*A. sativum*) is a tropical fruit common in Nigeria and other African countries. The leaf of the plant is biodegradable and renewable. The corrosion inhibitive properties of *Ananas A. sativum* for aluminum corrosion in acidic solutions using weight loss and hydrogen evolution methods at 303–333 K has shown it is one of the efficient green inhibitors.^[44]

The general mechanism for the corrosion of aluminum in acid was reported by Nguyen and Foley^[45] as follows:

Complexation reaction between the anion present and the hydrated cation is the controlling step in the metal dissolution (Eq. 6).^[44] In the presence of chloride ions, the reaction will be as follows:

Soluble complex ion is formed, which results in metal dissolution.

The crude extract of *A. sativum* acts as a corrosion inhibitor for aluminum in acidic medium. Inhibition efficiency of the extract increases with increase in the concentration of the inhibitor and also with an increase in temperature.^[44] The corrosion inhibition of *A. sativum* according to the authors could be due to the adsorption of the phytochemical constituents of the extract on the metal surface and blocking of its active sites by the phenomenon of chemical adsorption.^[44,45]

Cationic surfactant (1,1 lauryl amido propyl ammonium chloride) was studied as a corrosion inhibitor for aluminum in HCl solution in the temperature range of 10°C–60°C using weight loss, electrochemical impedance spectroscopy (EIS), and potentiodynamic polarization methods.^[46] Similar to other inhibitors, the surfactant showed that the corrosion inhibition of aluminum occurs through adsorption of the surfactant on the aluminum surface without modification of the corrosion process mechanism and exhibits anodic inhibitor characteristics. The surfactant's inhibition efficiency decreased with increase in temperature, but increased with an increase in the surfactant concentration. Also, the experimental data from the study fits into the Frumkin isotherm.

As earlier mentioned, the protection of aluminum alloys from corrosion in several media depends on the passive films formed on their surfaces. An alkaline solution is typically known to render the oxide film on aluminum surface non-protective. This is because OH-ion dissolves this surface oxide film and metal surface establishes a more negative potential, which leads to the formation of aluminate ion.^[47]

Neolamarckia Cadamba (*f. Rubiaceae*), also known as kadamba, is a tropical tree native to the India on the slopes of evergreen forests up to 500 m.^[48] The chemical constituents of *f. Rubiaceae* are pentacyclic triterpenic acid isolated from the stem bark of *f. Rubiaceae* named cadambagenic acid and tannins.^[49] Along with this acid are quinovic acid and β -sitosterol,^[50] which have constituents such as π -bonds and heteroatom (oxygen).^[48] The adsorption process of *f. Rubiaceae* occurs by the electrostatic interaction between the constituents of inhibitors and the charged molecule or by the interaction of unshared electron pairs of inhibitor molecules. The inhibiting study of this extract was conducted to test its effect on aluminum alloys using weight loss measurement. The report of the study showed *f. Rubiaceae* extract to be effective as a corrosion inhibitor for aluminum alloys in 1 M NaOH solution. The inhibition efficiency increased with increase in the extract concentration and decreased with increase in temperature.^[49] The adsorption of *f. Rubiaceae* bark extract on aluminum alloys surfaces followed the Langmuir adsorption isotherm, while polarization study revealed that it is a mixed-type inhibitor.

Abdel-Gaber et al.^[51] studied the inhibition of aluminum corrosion in 2 M NaOH solution with and without 0.5 M NaCl using *Ambrosia maritime*, L. (Damsissa) extract as an inhibitor. This study was carried out using chemical gasometric and electrochemical techniques. The results obtained from the chemical gasometric method showed that the addition of chloride ions or *Ambrosia A. maritime*, L. extract to NaOH solution decreased the hydrogen gas evolution. The electrochemical technique results, on the other hand, indicated that the presence of chloride ion in NaOH solution delayed the aluminum's anodic dissolution below the pitting potential. The results showed that *damsissa* extract acts as a mixed-type inhibitor. This is shown in the influence that the presence or absence of chloride ion exhibited in the delayed anodic dissolution of aluminum as well as the generation of hydrogen gas at the cathode. The authors also observed that there was a decrease in the limiting current with increasing *Ambrosia A. maritime*, L. extract concentration, which indicated a diffusion controlled anodic process. Also, application of a proposed equivalent circuit for the analysis of impedance spectra confirmed *Ambrosia A. maritime*, L. extract as an efficient corrosion inhibitor for aluminum in alkaline and was found to be more effective with the addition of chloride ions than in its absence.

The dissolution of aluminum oxide films which usually results in the corrosion of aluminum in chloride media is a result of the adsorption of chloride ions that react with aluminum cations in the oxide lattice, thus leading to soluble aluminum hydroxychloride ($\text{Al}_2\text{Cl}(\text{OH})_3$) salt formation.^[52–58] Many studies had been conducted on the protection of the aluminum and its oxide films in various corrosive chloride media.^[11,55,57] Among the researchers were Yamaguchi and Yamamoto,^[55] who investigated the adsorption of the poly(1,5-naphthalenediol) inhibitor on the aluminum surface in chloride media. In this study, the inhibitor showed efficient adsorption property forming a complex with the aluminum surface. Poly(1,5-naphthalenediol) inhibitor formed Al-O bond, which results in the inhibition of aluminum corrosion.

Peter^[32] carried out a study on the corrosion protection of AA2024-T3 in 0.1 M NaCl with and without the addition of Ce (III) chloride, Ce(III) nitrate, Ce(III) acetate, and Ce(IV) sulfate as inhibitors using immersion and electrochemical techniques. The inhibition efficiency of the cerium salts was reported to be in the range Ce(III) acetate > Ce(III) chloride > Ce(III) nitrate, while Ce(IV) sulfate was observed not to inhibit corrosion of the aluminum alloy studied. The inhibition efficiency of Ce salts for the alloy was said to depend on the type of substrate, salt concentration, and type of anion.

Lamaka et al.^[11] studied the corrosion inhibition of AA2024 aluminum alloy in chloride solutions using organic (about 16) inhibitors such as salicylaldehyde, 8-hydroxyquinoline, and quinaldic acid. The study was

conducted using electrochemical corrosion tests methods, scanning electron microscopy (SEM), X-ray photo electron spectroscopy (XPS), and scanning Kelvin probe force microscopy (SKPFM), and found the inhibitors to be effective. The authors reported that chemisorption and precipitation of complexes occurred on the alloy surface including active S-phases, thus, blocking the extension of the corrosion processes. The inhibiting action was said to be a result of suppression of the Mg, Cu, and Al dissolution from the corrosion active intermetallic zones.

Another study on the corrosion inhibition of AA2024 using sodium decanoate as an inhibitor was carried out by Boisier et al.^[58] Electrochemical techniques were used in analyzing the corrosion resistance of the aluminum alloy in NaCl solution while studying the characteristics of the inhibition mechanisms for varied pH and NaCl concentrations. The inhibitor exhibits an ability to form hydrophobic films on the alloy, thereby protecting it by limiting galvanic coupling between the surrounding matrix and the intermetallic particles, and also prevent chloride ion attack of the oxide layer.

Zuo et al.^[59] in their study on the inhibition of AA2024 aluminum alloy in an alkaline medium using surfactant sodium oleate showed that the inhibitor has two different effects on the corrosion inhibition of the aluminum alloy. The results obtained by the authors indicated that OH^- was formed by partial hydrolysis of $\text{C}_{17}\text{H}_{33}\text{COO}^-$ ions in solutions. The formation of OH^- increased the cathodic reaction rate, which then enhanced the formation of $\text{Al}(\text{OH})_3$ on the aluminum alloy surface. Secondly, $\text{C}_{17}\text{H}_{33}\text{COONa}$ was adsorbed on the surface of the aluminum alloy by chemisorptions or electrostatic adsorption to form barrier films, which further prevents the corrosion process and chloride ions attack. The inhibitor studied was effective in protecting AA2024 from pitting and uniform corrosion and also promote passivation of aluminum alloy in a lower concentration of NaCl, but could not promote passivity in 3.5 wt% NaCl solution. Furthermore, surfactant sodium oleate reduced pitting initiation tendency in AA2024 and the sensitivity of pitting corrosion.^[59] The addition of lower concentration of inhibitor showed good inhibition efficiency while showing a little re-passivation effect on initiated pits.

The inhibitive effect of *Euphorbia hirta* leaf extracts on corrosion of aluminum alloy in HCl and NaOH solutions were carried out using the gravimetric technique at temperatures of 30°C and 60°C.^[60] The results obtained showed the leaf extract to exhibit better inhibition efficiency in HCl than NaOH. The Langmuir isotherm best described the adsorption characteristics of the leaf extract, the values of the free energy of adsorption were obtained from the isotherm parameters, and they showed that the inhibitor exhibits a spontaneous adsorption process.

The corrosion inhibition of AA8011 aluminum alloy was studied in H_2SO_4 solutions using *Newbouldia leavis*

leaf extract by gravimetric measurements.^[61] The inhibition efficiency of the inhibitor depended on the time of exposure of the alloy in the acidic solution as well as the concentration of the inhibitor. The obtained experimental data fitted to the Langmuir adsorption isotherm, while the value and sign of Gibb's free energy of adsorption indicated a physical adsorption mechanism of the inhibitor molecules.

Nwosu and Osarolube^[62] carried out a study on the corrosion inhibition of aluminum alloy (Al-Si-Cu-Zn-Mg) in 0.75 M KOH solution at room temperature using *Xylopia aethiopica* seed extract by gravimetric technique. It was revealed that the inhibitor surface coverage increased linearly with the increase in the inhibitor concentration. The highest inhibition efficiency value of about 88% was obtained at 0.4 mg/l concentration of the inhibitor. The experimental data fitted in the Langmuir adsorption isotherm indicated that the mechanism of adsorption was physisorption, while Temkin isotherm models showed that lateral attractions exist between the inhibitor molecules and the surface of the alloy. Flory-Huggins isotherm model indicated that the inhibitor displaced water molecules present on the metal surface.

The inhibiting effect of lavender oil on Al-3Mg alloy in 3% NaCl solution was investigated by Halambek et al.^[63] using weight loss, polarization measurements, and microscopy method. The lavender oil was seen to reduce the corrosion rate even at elevated temperature. The Langmuir's adsorption isotherm also confirmed the adsorption characteristics of the inhibitor to be similar to other inhibitors.

Mishra and Balasubramaniam^[64] investigated the effect of LaCl_3 and CeCl_3 inhibitors in 3.5% NaCl solution on the corrosion resistance of the AA2014 aluminum alloy. The results from the study revealed that the corrosion rate decreased by the order of magnitude, while a significant increase was observed in the polarization resistance with the addition of 1000 ppm concentration of LaCl_3 and CeCl_3 . Microscopic study of the corroded alloys using SEM and Time of Flight Secondary Ion Mass Spectroscopy (ToF-SIMS) coupled with EIS measurements showed the formation of a complex oxide film of aluminum and cerium incorporating the organophosphate component on the surface of the alloy. Cerium diphenyl phosphate ($\text{Ce}(\text{dpp})_3$) has shown to be a strong corrosion inhibitor for aluminum alloys such as Al-Cu-Mg alloy (AA2024-T3 and AA7075) in chloride solutions.^[65-67] Mishra and Balasubramaniam^[64] proposed that the formation of a thin complex film consisting of hydrolysis products of the aluminum oxide and $\text{Ce}(\text{dpp})_3$ compound leads to the inhibition efficiency of the inhibitors.

Helal and Badawy^[68] studied the corrosion inhibition of Al-Mg-Zn alloy in stagnant naturally aerated chloride free neutral solutions using amino acids (phenylalanine) as corrosion inhibitors by the polarization technique and electrochemical impedance spectroscopy. Phenyl alanine

was found to show inhibition efficiency of about 93% at a concentration of $0.002 \text{ mol dm}^{-3}$. The Gibb's free energy of the adsorption process showed a physical adsorption of the inhibitor molecules on the surface of the aluminum alloy.

A work by Zhao et al.^[69] was focused on studying two different inhibitors [triazinedithiol inhibitors 6-diallylamino-1,3,5-triazine-2,4-dithiol monosodium (DAN) and 6-dibutylamino-1,3,5-triazine-2,4-dithiol monosodium (DBN)] as corrosion inhibitors for aluminum alloy (AA5052) in a 1 M HCl solution. Weight loss, electrochemical, and microscopy (SEM) techniques were applied in the study. The inhibition efficiency of DAN and DBN increased with

increase in inhibitor concentration, and the results obtained in all the methods used in testing the inhibition efficiency of the inhibitors were in agreement. The inhibitors exhibited mixed-type inhibiting properties while predominantly delaying the cathodic reaction, and the adsorption processes of both inhibitors fitted in the Langmuir adsorption isotherm. The inhibitors were more inclined to chemisorption mechanism at 30°C , and the calculated Gibb's free energy values showed that the inhibitors adsorbed spontaneously on the surface of the aluminum alloy.

Table 1 gives an overview of additional inhibitors that were used for the corrosion inhibition of aluminum and its alloys in different media.

Table 1 Summary of additional inhibitors

Inhibitors	Alloy	Media	Inhibition efficiency/effect	Reference
0.1–0.5 g/l Leaves extract of <i>Ficus sycomorus</i>	Al	1 M HCl	An inhibition efficiency of 98.92% was achieved with 0.5 g/L of the inhibitor after 4 h of exposure at 30°C . The free energy of adsorption ($\Delta G_{\text{ad}}^\circ$) has negative values which indicate a spontaneous adsorption of the inhibitor on the aluminum alloy's surface.	[70]
0.25–5 wt% Ceria doped polyvinyl chloride nanofiber	Al	0.1 M HCl	The inhibition efficiency increased with increasing concentration in the range 52%–85.7%. The maximum displacement E_{corr} was 37 mV. This value indicates that the inhibitor is mixed-type.	[71]
200–1000 ppm <i>Lawsonia inermis</i>	AA5083	Sea water	An optimum inhibition efficiency of 93% was obtained at 600 ppm, but decreased afterward. The difference in the E_{corr} of the absence and presence of inhibitor was 34 mV indicating that the inhibitor <i>L. inermis</i> is a mixed-type inhibitor.	[72]
0.1–0.5 g/l Leaves extract of African breadfruit	Al	1M H_2SO_4	78.56% Inhibition efficiency was obtained at 30°C using 5 g/L of the inhibitor. The corrosion inhibition was by physical adsorption mechanism and data fits in the Freundlich adsorption isotherm model.	[73]
20%–100% <i>Camellia Sinensis</i> (green tea)	Al	0.8 M H_2SO_4	Optimum inhibition efficiency (35%) was reached with 20% concentration of inhibitor on the eighth day. Negative inhibition efficiency values were obtained during the first few days of the experiments with both 80% and 100% concentrations. However, inhibition was achieved for the greater part of the experiment.	[74]
Areca nut seed extract		0.5 M HCl	The corrosion rate increased with increase in time and the inhibitor decreased corrosion current densities through a mixed-mode mechanism.	[75]
0.004 M 3 Decanoyl amino-propyl-ethyl-dimethyl-ammonium iodide (amido-amine based cationic surfactant)	AA1050	0.5 M HCl	Corrosion inhibition increased with increase in concentration from 19.98%–90.07%. The negative $\Delta G_{\text{ad}}^\circ$ values were obtained, which indicate a spontaneous adsorption process.	[76]
0.001–0.05 M Rare earth salts, CeCl_3 , LaCl_3 , $\text{Ce}(\text{NO}_3)_3$, and $\text{La}(\text{NO}_3)_3$	AA7075-T6	0.1M NaCl	CeCl_3 exhibited the highest inhibitory efficiency followed by the mixtures of CeCl_3 and LaCl_3 .	[77]

(Continued)

Table 1 Summary of additional inhibitors (*Continued*)

Inhibitors	Alloy	Media	Inhibition efficiency/effect	Reference
3 mM potassium chromate (K_2CrO_4), sodium silicate (Na_2SiO_3), and sodium vanadate ($NaVO_3$)	AA5083-H116	3.5 wt% NaCl	The inhibitors showed a suppression of the cathodic reaction, with chromate causing mixed-type inhibition on the alloy without the altered surface layer (ASL). The inhibitors gave a cathodic inhibition with chromate exhibiting additional anodic inhibition on sensitized alloy without an ASL.	[78]
4 mM Vanadate	AA2024-T3	0.1 M NaCl, DI water and dry air	Trenching occurred around the S phase particles when solution temperature increased to 70°C and above from 10°C. The S phase was protected by a vanadate-bearing film.	[79]
0.5, 1.0, 1.5, and 2.0 g/mL ferrous gluconate	Al alloy	0.05M NaCl	The minimum inhibition efficiency was achieved at 1.5 g/mL concentration of the inhibitor, while the optimum inhibition efficiency was achieved with 1.0 g/mL inhibitor concentration. The data from the inhibition test fits Langmuir adsorption isotherm. The potentiodynamic polarization results showed that the inhibitor is a mixed-type inhibitor.	[80]
50, 100, 150, and 200 ppm Benzene sulphonic acid	Al	0.5 and 1 M NaOH	The inhibitor molecules were chemically adsorbed to the metal surface at 120 min and below of the reaction period. Mixed adsorption of chemisorptions–physisorption mechanism was seen between 120 min and 150 min.	[81]
Chalcone derivatives [3-(4-hydroxyphenyl)-1-phenylprop-2-en-1-one (inhibitor 1) and 3-(4-hydroxyphenyl)-1-(4-nitrophenyl)prop-2-en-1-one] (inhibitor 2)	Al	0.5 M HCl	Inhibitor efficiency for inhibitors 1 and 2 at 21×10^{-6} M concentration were 85.9% and 95.7%, respectively. The inhibition efficiency decreased with increase in the temperature. The inhibitors showed mixed-type inhibition characteristics.	[82]
Penicillin G(I), methicillin (II), and nafcillin (III)	Al	1M HCl	The inhibitors acted as mixed-type inhibitors. The maximum inhibition efficiency of 85.67% was exhibited by nafcillin (III), and the minimum inhibition efficiency of 42.07% was shown by penicillin G (I). The adsorption data fit the Frumkin adsorption isotherm.	[83]
0–100 ppm Curcumine Longa (1, 7-bis(4-Hydroxy 3-methoxyphenyl)-1, 6-heptadiene 3, 5-dione)	Al	1 M HCl	Optimum inhibition efficiency value of 89.60% was reached at 100 ppm concentration. The polarization study showed the inhibitor to act as a mixed-type inhibitor, while EIS study showed that it inhibits aluminum corrosion by getting adsorbed at metal/electrolyte interfaces.	[84]
600–1800 ppm <i>Ricinus communis</i> oil	Al	0.1 M Na_2CO_3	At 1600 ppm inhibition concentration, an optimum inhibition efficiency of 87% was reached. The efficiency increased with the increase in the concentration and decreased with the increase in the temperature. The inhibitor was considered as a mixed-type inhibitor.	[85]
0.25–1g/L <i>Thymus algeriensis</i> extract	AA2024	Aerated 1 M HCl	The inhibition efficiency of the inhibitor increased with increasing extract concentration and reached 78.7% at 0.75 g/L. The inhibition efficiency was independent of temperature. The presence of inhibitor increased the activation energy of the corrosion process. The inhibition efficiency synergistically increased on the addition of potassium iodide with the inhibitor.	[86]

CONCLUSION

This study showed that corrosion inhibition of aluminum alloys depends on the type of electrolyte, the temperature of the electrolyte, the concentration of the inhibitor, and the type of inhibitor. The inhibitors for corrosion inhibition of aluminum and its alloys exhibit mostly mixed-type and cathodic inhibition effect, though some have anodic inhibition characteristic depending on the medium of inhibition. Physical adsorption and electrostatic attraction are common adsorption effect of corrosion inhibition of aluminum alloys as seen in the Langmuir adsorption isotherms of various inhibitors studied. In addition, Gibb's free energy values indicated that the inhibitors studied for the corrosion inhibition of aluminum alloys undergo spontaneous adsorption process. Corrosion inhibition of aluminum alloys using various inhibitors in different media results from complexation reaction of hydrated cation and the anion present in solution. In chloride environment, solution complexation is formed which leads to the dissolution of metal and Al-O bond is formed which further prevents aluminum alloys from corrosion.

Corrosion of Aluminum and Its Alloys

T. David Burleigh

New Mexico Tech, Socorro, NM, United States

Abstract

Corrosion of aluminum is a chemical reaction with its environment leading to the deterioration of its properties. This article addresses corrosion of aluminum including why it corrodes. Included in this review are the following topics: Pourbaix Diagrams, electrochemistry of corrosion, effect of chlorides on corrosion rates, forms of corrosion and their prevention, microbiological corrosion prevention, and testing.

Keywords: Electrochemistry; Galvanic; Inhibitors; Microbiological corrosion; Pourbaix diagrams; Stress corrosion cracking (SCC).

INTRODUCTION

This chapter examines the issues concerning what is corrosion and why does aluminum corrode. Corrosion is the chemical reaction of a metal, in this case aluminum, with its environment, which leads to the deterioration of the properties of the aluminum. Aluminum is a very reactive metal, but it is also a passive metal. This contradictory nature is explainable because nascent aluminum reacts with oxygen or water and forms a coherent surface oxide which impedes further reaction of aluminum with the environment (Fig. 1). Aluminum is chemically very reactive. For example, powdered aluminum is used as rocket propellant for propulsion of the space shuttle's solid fuel rockets. Additionally, the reaction of aluminum with water releases a tremendous amount of energy:

In the above equation, one pound of aluminum reacting with water can release the energy equivalent to nine pounds of dynamite. Figure 2 illustrates that aluminum metal is converted from the bauxite ore only by the input of a large amount of electrical energy and heat. In turn, aluminum metal has a similar driving force to return to its hydroxide state. Corrosion is the reaction of aluminum with water and the subsequent deterioration of its properties. Corrosion, by definition, is a slow process, requiring days or years to occur to a noticeable extent, as opposed to similar electrochemical reactions such as etching, brightening, or anodizing which occur in minutes or less.

DISCUSSION

The Pourbaix Diagram for Aluminum

The corrosion of aluminum requires the presence of water. The chemical equilibrium of aluminum and water is best illustrated by the Pourbaix Diagram shown in Fig. 3.^[1] The Pourbaix diagram, also known as the potential-pH diagram, shows the equilibrium phases for the aluminum-water system at different pHs and potentials. The pH (*x*-axis) varies from acidic at low pH to caustic at the high pH. The electrochemical potential (*y*-axis) is measured against the hydrogen electrode, with the negative potentials being chemically reducing, while the positive regions are chemically oxidizing. The region of water stability is bounded by the dashed lines labeled (a) and (b). Line (a) is the hydrogen line, below which water is no longer stable and decomposes into hydrogen and OH⁻ (alkalization). The (b) line is the oxygen line above which water decomposes into oxygen and H⁺ (acidification). The world's natural environments generally exist within the regions where water is stable, between lines (a) and (b). In acidic conditions (low pH), aluminum will dissolve as Al³⁺, and in caustic conditions (high pH) aluminum will dissolve as AlO₂⁻. In neutral pHs, from 4 to 8, the hydroxide of aluminum is insoluble and will form a passive film on the aluminum's surface and protect the aluminum, as shown in Fig. 4. Between these regions of passivation and corrosion in Fig. 3 are four parallel lines labeled -6, -4, -2, and 0, which denote the chemical activity (on the log scale) of the ionic species. Chemical activity is roughly proportional to the concentration. The 0 line denotes a unit

Fig. 1 Aluminum is passivated in air by a thin film of aluminum oxide

Fig. 2 Refining produces aluminum metal, but corrosion returns the metal back to aluminum hydroxide

chemical activity (10^0) which would be a saturated ionic solution in contact with the solid phase. The -6 denotes a very dilute solution (10^{-6}), roughly 1 ppm of the ionic species in contact with the solid phase.

By using the Pourbaix diagram, one can explain why aluminum corrodes (dissolves) in liquid concrete, but is stable in solid concrete (assuming no salt is present). Concrete has a $\text{pH} = 13$, which on the Pourbaix diagram corresponds to the region where AlO_2^- with an activity of 0.01 (10^{-2}) is stable with solid gibbsite (hydrargillite). In liquid flowing concrete, it is difficult to maintain an activity of 0.01 of AlO_2^- , so the aluminum continuously dissolves. However, in solid concrete, solid state diffusion is very slow, and the aluminum/concrete interface can become saturated in ionic species, which are immobile, and prevent further dissolution.

The Pourbaix diagrams illustrate that in fresh water aluminum will be passive, assuming there are no halide ions such as chlorides present. (The effect of chlorides is described in later section.) The Pourbaix diagrams in Fig. 3 and 4 illustrate that aluminum will dissolve in both acids and bases. Figure 5 shows experimental data from

Fig. 3 The Pourbaix diagram for aluminum and water illustrates the stable phases for the different potentials and pHs^[1]

Fig. 4 The Pourbaix diagram is redrawn showing the regions of corrosion, passivation and immunity, by assuming passivation by a film of gibbsite, $\gamma\text{-Al}(\text{OH})_3$

Hatch^[2] that aluminum dissolves rapidly both in high pH solutions (alkaline or caustic) and in low pH solutions (acids) due to the instability of the aluminum oxide and hydroxide films. (There are exceptions such as in sodium disilicate (i), where the aluminum passivates with insoluble silicate compounds. In concentrated nitric acid (a), the dissolution rate is also very slow, and the passivation mechanism is not understood.) A word of caution about using these Pourbaix diagrams: first, these diagrams show the equilibrium state, but predict nothing about the rates of reaction (fast versus slow). Second, even if the bulk solution has a neutral pH, aluminum can still corrode via localized corrosion since pits or crevices can have a different pH and chloride concentration than the bulk solution.

Electrochemistry of Corrosion

Aluminum corrosion is an electrochemical reaction, not simply a chemical reaction. Electrochemical means that the reaction depends on a transfer of electrons from one site, the anode, where aluminum is dissolving and releasing

electrons, to a second site, the cathode, where the electrons are consumed (Fig. 6). The reaction for the anodic dissolution of aluminum is shown in Eq. 2

The cathodic reaction on the other hand consumes the electrons. In water there are two possible cathodic reactions. If oxygen is present, the cathodic reaction is the reduction of oxygen in which oxygen is reduced to hydroxyl anions, as shown in Eq. 3. This cathodic reaction will cause an increase in the pH at the surface:

The reduction of oxygen is a fairly rapid reaction when it occurs on impurities such as Fe or Cu precipitates in the aluminum matrix. For this reason, single phase aluminum alloys will have greater corrosion resistance than aluminum alloys which contain second-phase intermetallic particles.

If there is no oxygen present, the second possible cathodic reaction in water is hydrogen evolution:

This reaction is generally slow on aluminum except in acidic solutions or unless a large negative potential is applied to the aluminum. This second cathodic reaction also increases the pH at the surface of the aluminum. When bare aluminum is immersed in water, its surface will initially become alkaline due to these cathodic reactions.

Once the aluminum cation has dissolved into the aqueous solution, it may diffuse to another area where it precipitates from the solution as a gelatinous aluminum hydroxide (Eqs. 5 or 6). Upon drying and dehydrating, the hydroxide gel forms the white crystalline corrosion product powder found on dry corroded aluminum.

Fig. 5 The effect of pH on corrosion of 1100-H14 alloy by various chemical solutions^[2]

Fig. 6 The dissolution-precipitation mechanism of aluminum corrosion. The aluminum dissolves as a cation at the anode. The electrons travel through the metal to the cathode where they are consumed by the cathodic reaction. The aluminum cation and the hydroxyl anion combine in the liquid and precipitate as a solid

In both of the above reactions, the precipitation of aluminum hydroxide leads to acidification of the region. The corrosion mechanism of aluminum is known as Dissolution-Precipitation Mechanism (Fig. 6). Figure 7 from Wefers,^[2] illustrates the surface of aluminum after exposure to water at 62°C. The aluminum oxide is covered with a gelatinous hydroxide. On the top surface, crystals of bayerite begin to grow. Above 70°, boehmite replaces the bayerite as the stable phase.^[3] Aluminum corroded in salt-water can develop a thick hydroxide gel which will form a mud crack pattern when dried, as shown in Fig. 8.^[4]

Effect of Chlorides on Corrosion Rates

Chlorides (e.g. NaCl) dissolved in water, can accelerate the corrosion of aluminum. The chlorides increase the conductivity of the water, and they assist in the dissolution process. As shown above in Eq. 6, when aluminum cations precipitate, the aqueous solution becomes acidic with positively charged hydrogen cations (H^+). These positive cations attract negative anions such as hydroxyls (OH^-) and chlorides (Cl^-). The chloride anions are smaller and more mobile and can diffuse faster than the hydroxyls, thus the anodic site becomes acidic and concentrated in chlorides, that is, dilute hydrochloric acid. (Not to be confused with the cathodic site which is becoming more alkaline, Eqs. 3 and 4. The passive film on aluminum is unstable in dilute hydrochloric acid and can not regenerate. Thus wherever the passive film is defective, the underlying aluminum base metal begins to dissolve. This reaction is auto-catalytic (self-accelerating) because the dissolution-precipitation of aluminum causes more chloride anions to be attracted to the site. The aluminum can combine with the chlorides to form AlCl_3 (Eq. 7) which is very soluble (449 gm can dissolve in one liter of water at 25°C^[5]), in contrast to $\text{Al}(\text{OH})_3$

Fig. 7 (A) The surface of aluminum after one day in hot water (62°C.) (B) Schematic of the multilayered hydroxides film on aluminum^[3]

which is insoluble in neutral water (10^{-8} g dissolve in one liter of water at 25°C ^[5]).

As the concentration of chlorides is increased, the corrosion mechanism can change from passivity to pitting or to anodic brightening or active dissolution, as shown in Fig. 9 from T. P. Hoar.^[6] In a sense, pitting is anodic brightening on a localized scale (inside the pit). T. P. Hoar^[6] proposed that chloride clusters form about the aluminum cations, and these can diffuse a short distance and then react with hydroxyls or water, and precipitate out as aluminum hydroxide, as shown in Fig. 10 and Eq. 8.

Fig. 9 The concentration of anion (e.g. Cl^-) can change the corrosion mode from passivity, to pitting, to active dissolution, to anodic brightening^[6]

Source: With permission from The Electrochemical Society.

Fig. 10 The chloride anions accelerate the dissolution of aluminum by chloride clusters which diffuse from the anodic site, and then react with hydroxyls and precipitate out of solution

Chloride anions are released from the cluster and return to the pit to continue the dissolution-precipitation reaction. As verification of this model, Wong and Alkire^[7] measured the solution in the aluminum pits and demonstrated that they contained aluminum hydroxyl-chlorides, $\text{AlCl}_x(\text{OH})_{3-x}$. Thus an entire range of aluminum hydroxyl-chlorides are possible.

FORMS OF ALUMINUM CORROSION AND THEIR REMEDIES

Aluminum alloys may corrode via several different pathways. Recognizing the pathway or the forms of aluminum corrosion is an important step to determine the appropriate remedy for each problem.

Uniform Corrosion

General corrosion, or uniform corrosion (Fig. 11), occurs in the solutions where pH is either very high or very low, or at high potentials in electrolytes with high chloride concentrations. In acidic (low pH) or alkaline (high pH) solutions, the aluminum oxide is unstable and thus non-protective. Figure 5 demonstrated that aluminum dissolves rapidly in both high pH (e.g. caustic etching in sodium hydroxide) or low pH (e.g. dissolution in hydrochloric acid). Notably there are a few exceptions, as seen in Fig. 5. The second case of uniform dissolution, can occur in a high chloride concentration with a high applied potential (voltage). This is shown in Fig. 9 as anodic brightening.

The remedy for uniform corrosion is to change the electrolyte, use cathodic protection, add inhibitors, or replace the aluminum with a more corrosion resistant alloy. These options are discussed in detail in Section 4.

Galvanic Corrosion

Economically, galvanic corrosion creates the largest number of corrosion problems for aluminum alloys. Galvanic corrosion, also known as dissimilar metal corrosion, occurs when aluminum is electrically connected to a more noble metal, and both are in contact with the same electrolyte (Fig. 12). The Galvanic Series in Flowing Seawater from the ASM Handbook Volume 13,^[8] is shown in Fig. 13. The aluminum alloys exhibit corrosion potentials between -0.6 V and -0.8 V versus the Saturated Calomel Electrode (SCE). The exact corrosion potential of an

Fig. 11 Uniform corrosion of aluminum

Fig. 12 Galvanic corrosion of aluminum in contact with a more noble metal, e.g. copper. The aluminum is the anode and dissolves preferentially, while the copper is the preferential cathodic site

aluminum alloy depends on its composition and heat treatment. Table 1 from Burleigh et al.^[9] shows a listing of the corrosion potentials of many aluminum alloys with different heat treatments. When an aluminum alloy is connected to copper, which has a corrosion potential of -0.1 V, then there will be a 0.5 V difference between the two metals. Aluminum will dissolve preferentially, and the released electrons will flow to the copper where they shall participate in either of the two cathodic reactions, oxygen reduction, or hydrogen evolution (Fig. 12). In galvanic corrosion, the surface area of the cathode (the copper in this example)

is a limiting factor. If the cathode surface area is reduced (by coating or by design), then the maximum cathodic current is correspondingly reduced.

A catastrophic form of galvanic corrosion can occur if mercury (Hg) contacts aluminum under aqueous chloride conditions. Mercury amalgamates with aluminum and in the presence of water and chlorides can produce voluminous gelatinous aluminum hydroxide. An unpublished story tells when mercury entered into a sewage treatment plant which had aluminum gates.^[10] The mercury corroded the gates with a combination of amalgamation, galvanic corrosion and liquid metal embrittlement (grain boundary attack), and the ensuing cathodic reaction (hydrogen evolution) was observed by the fizzing of the aluminum gates.

The 2000 series aluminum alloys contain > 1% Cu for precipitation hardening, and these copper precipitates (Al_2Cu) can act as cathodic sites which reduce the corrosion resistance of the alloy (the rate is limited by the low surface area of the precipitates). Constituent particles such as Al-Fe can also act as the cathodic sites. Alcladding, which will be described in detail in the next section, uses galvanic corrosion to protect the copper containing alloys.

The remedy for galvanic corrosion begins on the drawing board. Good design can eliminate many galvanic corrosion problems. Ideally one should not put galvanically dissimilar metals in direct contact (see Table 1). If this can not be avoided, then an electrical insulator would prevent electrical transfer. If direct contact is required (e.g. rivets and fasteners) then water should be excluded (with sealants), the cathodic area should be coated, and the product should be designed to facilitate the water run-off.

Crevice Corrosion

Crevice corrosion requires the presence of a crevice, a salt water environment, and oxygen (Fig. 14). The crevice can result from the overlap of two parts, or the gap between a bolt and a structure. When aluminum is wetted with the saltwater and water enters the crevice, little happens initially. Over time, inside the crevice oxygen is consumed due to the dissolution and precipitation

Fig. 14 Crevice corrosion can occur in a saltwater environment if the crevice becomes deaerated, and the oxygen reduction reaction occurs outside of the crevice mouth. Under these conditions, the crevice becomes more acidic, and corrosion occurs at an increasing rate

of aluminum (Eqs. 2, 3, and 5). If the crevice is narrow and the inward diffusion of oxygen is restricted, oxygen becomes depleted, and the crevice becomes acidic via the precipitation reaction in Eq. 6. This acidic environment contains H^+ cations which attract anions in order to maintain the electrical neutrality of the crevice environment. The hydroxyl anions, OH^- , diffuse slower and loose the crevice race to the faster Cl^- anions. The crevice, which was originally neutral gradually becomes acidic due to the formation of a dilute hydrochloric acid environment. The anodic dissolution of aluminum accelerates inside this acidic crevice, and the cathodic reaction, oxygen reduction, occurs outside of the crevice mouth. Crevice corrosion is often called “autocatalytic” since it is self-accelerating.

The crevice in the above description is acidic. Crevices can be instead slightly alkaline if the outside of the crevice has a good coating or is always dry. If the oxygen reduction reaction (Eq. 3) can not occur external to the crevice mouth, then the cathodic reaction must occur inside the crevice. In the absence of oxygen, the cathodic reaction would be hydrogen evolution, Eq. 4 in an acid, or Eq. 9 in a neutral solution. This reaction would push the crevice alkaline, and corrosion would occur at a slower rate than the acidic crevice with the external cathode.

The best way to prevent crevice corrosion is also on the drawing board. The designer should eliminate crevices and gaps by continuous welding, or sealing the crevices with sealant, or allowing drainage. The outside should be coated to minimize the area available for the cathodic reaction. Maintenance by waxing or repainting minimizes the external cathodes, and seals the crevices which would prevent the occluded cells from initiating and growing.

Pitting Corrosion

Pitting corrosion is very similar to crevice corrosion. Pitting of aluminum alloys occurs if the electrolyte contains a low level of chloride anions, and if the alloy is at a potential above the “pitting potential.” Much research has been conducted on the pitting corrosion of aluminum (e.g. Schmutz and Frankel^[11]). The pitting potential of unalloyed aluminum in a $\text{NaCl-H}_2\text{O}_2$ solution is approximately -0.76 versus SCE.^[9] Figure 9 from Hoar^[6] (although highly generalized for all metals), illustrates that pitting occurs when the chloride anion concentration is too low for anodic brightening, but too high for complete passivity. Pitting initiates at defects on the surface of the aluminum, such as at second phase particles or on grain boundaries. (If a high potential is applied to aluminum, then the pitting is reported to occur randomly across the surface.) The potential can be affected by having oxygen present for oxygen reduction (Eq. 3) or galvanic contact with a more noble metal, or via an applied voltage.

Fig. 15 The pit initiates at defects, and growth occurs if an occluded cell forms

Embryo pits, which form and repassivate, occur rapidly over the surface of aluminum. This breakdown and repassivation produces an electrical noise which can be measured to give an estimate of the corrosion rate of the aluminum. Some of these embryo pits reach a critical size in which repassivation does not occur, and the pit continues to grow. This growth occurs because the pit becomes an occluded cell by the precipitation of its own corrosion product outside the mouth of the pit (shown schematically in Fig. 15). This occluded cell is similar to the crevices mentioned previously and is also acidic and high in chlorides. The dilute hydrochloric nature of the pit leads to continued dissolution. As the pit acidifies, hydrogen evolution becomes favorable as the cathodic reaction inside the pit, and the escaping hydrogen bubbles effectively pump out the AlCl_3 , which reacts outside the pit with water and precipitates the Al(OH)_3 . This action forms white corrosion chimneys which can be found on the surface of pitted aluminum as shown in Fig. 16 from the work of Burleigh, Ludwiczak, and Petri.^[12] For a detail description of the pitting process, a ten-step mechanism for the pitting of aluminum has been described by Reboul et al.^[13]

Although an individual pit may stop growing for a variety of reasons, some pits continue growing deeper over time. Figure 17 (data from Aylor^[14]) shows the pitting depth for samples of alloy 6061-T6 immersed in seawater at three different worldwide locations. The pit depth continually increases, although at a decreasing rate over the ten year exposure period.

Fig. 17 The pits continue growing in depth over the ten-year period of immersion in sea water^[14]

The best way to prevent pitting is to prevent the occluded cells from initiating and growing. This prevention can be achieved through regular maintenance of the surface, such as regular washing and polishing to remove dust particles, and waxing or repainting to seal occluded cells or defects. Bare aluminum which is regularly maintained by washing and buffing appears to last indefinitely in a semi-industrial exposure.^[15]

Intergranular Corrosion

Intergranular corrosion is a special form of corrosion characterized by the preferential attack of the grain boundaries. Intergranular (IG) corrosion is also referred to as intergranular attack (IGA). IG corrosion only occurs if the grain boundary regions are compositionally different from the bulk of the alloy. This compositional difference occurs during heat treating, aging, or welding by diffusion of atoms and precipitation of second phase particles.

Intergranular corrosion initiates often at the sites of crevice corrosion or pitting corrosion. The acidic pit

Fig. 16 These SEM micrographs show the corrosion chimneys which form over corroding pits during immersion in a $\text{NaCl-H}_2\text{O}_2$ solution. Cubic salt crystals are present on the surface. SEM photographs by Bob Petri^[12]

Fig. 18 The pitting corrosion forms an acidic environment which leads to preferential dissolution of the grain boundary regions^[12b]

Source: With permission from NACE International.

environment leads to the preferential attack of the grain boundary region, as illustrated in the schematic in Fig. 18. The two different mechanisms by which IG corrosion may occur are illustrated in Fig. 19. The first mechanism is the precipitation of a more active phase, for example Al-Mg at the grain boundaries in 5000 series alloys. On exposure to saltwater, this phase dissolves preferentially (Fig. 19a), leaving the bulk grains separated from each other. The second mechanism of IG corrosion occurs if a more noble phase precipitates at the grain boundaries, for example CuAl_2 in the 2000 or the 6000 alloys which contain copper. In this case, the areas adjacent to the grain boundaries are depleted of the copper, which makes them more reactive, and allows their dissolution in the acidic pit environment, leaving behind the grain boundary precipitates and the bulk matrix grains (Fig. 19b). This second mechanism is seen in the TEM micrograph in Fig. 20 where the TEM foil was etched in a dilute HCl solution.^[12] The grain boundary (white arrow) contains Al-Cu precipitates, which remain after the depleted grain boundary region is dissolved.

Fig. 20 TEM micrograph showing the preferential dissolution of the grain boundary region, leaving the Al-Cu precipitates suspended in the corrosion product. TEM photographs by Ray Kilmer^[12]

Source: With permission from NACE International.

Figure 21 shows different types of intergranular corrosion for different aluminum alloys.^[2]

Intergranular corrosion can be prevented by using a single phase alloy, however, this is not always possible. Proper heat treatments can minimize the differences in potential between the bulk alloy and its grain boundary. For example in the 6000 alloys, the T6 temper often shows better IG resistance than the T4 temper. If a 2000 alloy is solutionized and not quenched rapidly, then precipitates may form on the grain boundaries and lead to IGA. Adhesive bonding is preferable over welding since the welding causes uncontrolled heat treatments and precipitation of second phases in the heat affected zone (HAZ). Eliminating the sites of pitting or crevice corrosion will also stop the initiation of IG corrosion.

Exfoliation Corrosion

Exfoliation corrosion is a special form of intergranular corrosion which occurs when the grains are flattened by heavy deformation during hot or cold rolling, and where

Fig. 19 Intergranular corrosion can occur by either (a) the dissolution of a more active grain boundary precipitate; or (b) the dissolution of a depleted matrix around a more noble grain boundary precipitate

Fig. 21 Various types of intergranular corrosion: (a) cast structure; (b) wrought unrecrystallized structure; and (c) recrystallized structure^[2]

Source: With permission from ASM International.

no recrystallization has occurred. Exfoliation corrosion has the appearance of leaves of a book. Figure 22 (courtesy of Alcoa^[16]) shows a plate of alloy 7075-T6 after six years of seacoast exposure. The 0.75 in thick plate was machined to the mid-plane leaving a plate of 0.375 in thickness. This plate was exposed at the seacoast in the bare condition, and the left side swelled to approximately four times the original thickness. Exfoliation is characteristic for the 2000 (Al-Cu), 5000 (Al-Mg), and 7000 (Al-Zn) series alloys which have grain boundary precipitation or depleted grain boundary regions.

The remedy for exfoliation is similar to above for IG corrosion. To prevent the exfoliation of alloy 7075-T6, the newer alloy 7150-T77 can be substituted wherever 7075-T6 is used.

Erosion-Corrosion

Erosion-corrosion of aluminum occurs in high velocity water and is similar to jet-impingement corrosion. Figure 23

Fig. 22 Exfoliation of alloy 7075-T6 after six years seacoast exposure in the bare condition^[16]

Source: With permission from Alcoa.

Fig. 23 Erosion-corrosion of a water-cooled, alloy 6061-T6 heat sink used for cooling electronic equipment. The pH of the cooling water was > 9 which led to the dissolution of the aluminum

shows a water-cooled aluminum heat sink used for cooling electronic equipment. In this case, the closed-loop cooling water became alkaline with a pH > 9 , and severe erosion-corrosion occurred at the right-angle bends in the heat sink. Erosion-corrosion of aluminum is very slow in pure water, but is accelerated at pH > 9 , especially with high carbonate and high silica content of the water.^[16b,16c]

Aluminum is very stable in neutral water, however it will corrode in either acidic or alkaline waters as shown in the Pourbaix^[1] diagram in Fig. 3 and 4. Notice that at pH = 8.6, aluminum has an activity of 10^{-6} , or approximately a solubility of 1 ppm in water as AlO_2^- . With high velocity water which contains no AlO_2^- , the aluminum will be continually dissolving, trying to reach the activity of 10^{-6} . In addition, if the surface is abraded, the passive film will not be able to reform at pH > 9 .

Jones^[16b] examined the erosion-corrosion of aluminum alloy 8001 in high temperature, high pressure water. In distilled water (pH = 8.3), the erosion-corrosion was negligible (5 μm depth) after 24 hr. However, in distilled water with 50 ppm CaCO_3 , 10 ppm SiO_2 , and pH = 8.3, the erosion corrosion depth was 689 μm after 24 hrs. The carbonate and the silica interfered with the stable passive film growth on aluminum. Li^[16c] studied the effect of different solutions on the jet-impingement corrosion of aluminum alloy 1100. Jet impingement of tap water at pH = 7.1 showed no detectable corrosion after an hour at 12 ft/sec impact velocity. However, a 0.1 M Na_2CO_3 solution at pH = 11.7 showed a weight loss of 2.2 mg/hr under the same jet impingement conditions.

To prevent erosion-corrosion, one may change the water chemistry or reduce the velocity of the water, or both. For the water chemistry, the pH must be below 9, and the carbonate and the silica levels must be reduced. If the pH can not be changed, then another possibility is to saturate the closed-loop water with AlO_2^- to reduce the corrosion rate.

Stress Corrosion Cracking (SCC)

Stress corrosion cracking (SCC) is the bane of aluminum alloys. Sometimes very little corrosion is evident on the outer surface, but it is possible for a critical length stress corrosion crack to be extending deep into the structure, causing a rapid and unexpected failure. Figure 24^[16] shows stress corrosion cracks in sheet 2091-T3 after 8 days exposure at 28 ksi stress in the ASTM G44 alternate immersion test.^[17] In SCC, the external corrosion is minimal, but the cracks are significant. SCC requires three simultaneous conditions, first a susceptible alloy, second a humid or water environment, and third a tensile stress which will open the crack and enable crack propagation. (A compressive stress

Fig. 24 Stress corrosion cracks in a 2091-T3 sheet which was exposed for 8 days to the alternate immersion test (ASTM G44) at 28 ksi.^[16]

Source: With permission from Alcoa.

will close the crack and prevent SCC.) SCC can occur in two modes, intergranular stress corrosion cracking (IGSCC) which is the more common form, or transgranular SCC (TGSCC). In IGSCC, the crack follows the grain boundaries (Fig. 22 and 24). In transgranular stress corrosion cracking (TGSCC), the cracks cut through the grains and are oblivious to the grain boundaries (see Fig. 25 from Burleigh^[18]). Much research has been conducted on the subject of SCC of aluminum alloys. Review articles on the SCC of aluminum alloys have been written by Sprowls,^[19] Holroyd^[20] and Burleigh.^[21]

Figure 26^[22] shows the evolution of the alloys used for the upper wing skin plate for different aircraft over the years. A higher yield strength alloy provides more strength for less weight. The general trend to use higher strength alloys peaked in 1950 with alloy 7178-T651 used on the Boeing 707, then the industry changed to using lower strength alloys. The yield strength of the upper wing skin did not exceed the 1950 level until the Boeing 777 in the 1990s. The reason lower strength alloys were selected for the Boeing 747 and the L-1011 was that the aircraft designers chose an alloy with better SCC resistance rather than the higher yield strength. The pre-1950 alloys exhibited high yield strength but possessed poor SCC resistance.

The aerospace alloy 7079-T651 was designed in the 1950s to be SCC resistant forging alloy, but it proved instead to have exceptionally poor SCC resistance and has since been abandoned. The aerospace industry was initially misled by alloy 7079 because the development corrosion tests were conducted on smooth compact tension specimens tested for weeks or months in an alternate salt-water immersion test (ASTM G44^[18]). The stress corrosion crack took a long time to initiate on the smooth surface on alloy 7079-T6 compared to alloy 7075-T6 in the same test environment. Once a crack did initiate in 7079-T6, it grew very rapidly (Fig. 27 from the work of Hollingsworth

Fig. 25 Transgranular SCC of a 5182 soda can end. The blow-out occurred under hot humid storage conditions^[18]

Fig. 26 The aerospace industry initially chose stronger alloys for the upper wing skin plate until the 1950s when they reversed and went to a lower strength alloy with better SCC resistance. The 1950 strength levels were not exceeded until the 1990s^[22]

and Hunsicker^[23]) as compared to other aluminum alloys. When the 7079 forgings were put into service, they served for several years, and then suddenly cracked. As a consequence, new alloy development today relies on a multitude of corrosion tests rather than one test technique.

Notable in Fig. 28^[20] is that the SCC cracks will propagate in distilled water, although a hundred times slower than in saturated NaCl solution. Figure 29 illustrates that as the relative humidity increases from 1% to 100%, the crack velocity for 7075-T6 also increases 100 times. SCC of the 7000 series alloys is considered by many researchers to be a hydrogen-induced cracking.^[20,21] For most aluminum alloys, the crack propagates along the grain boundaries, thus it is named intergranular stress corrosion cracking (IGSCC). For alloy 2024-T3, the cracking mechanism is considered to be due to anodic dissolution of the grain boundary regions as opposed to the hydrogen-induced cracking.^[21] The IGSCC crack growth occurs perpendicular to direction of the applied stress because the applied stress opens the properly oriented grain boundaries. SCC cracks predominantly grow along high angle grain boundaries. The stresses in the short transverse direction (Fig. 30) have much lower SCC threshold levels than stresses in the other directions (Fig. 31).

Transgranular stress corrosion cracking (TGSCC) has been observed occasionally on aluminum alloys. It was

Fig. 28 The stress corrosion crack will propagate in distilled water as well as in NaCl solutions^[20]

first reported on alloy 7050-T73651 (Lifka^[24]) and has since been documented on alloy 5182 soda can ends which blew out during storage in the high humidity summer months (Burleigh^[18]). TGSCC is characteristic by having a fan-shaped fracture pattern (Fig. 25) sometimes with

Fig. 31 Stresses in the short transverse direction have the lowest threshold stress for SCC^[23]

Source: With permission from ASM International.

fatigue-like striations. TGSCC is believed to be related to hydrogen embrittlement.

For prevention of SCC, one can change the alloys or the temper (use 7150-T77 instead of 7075-T6), reduce the stress level, remove the aqueous environment, redesign the part, or use better coatings.

Corrosion Fatigue

Corrosion fatigue can occur when an aluminum structure is repeatedly stressed at low stress levels in a corrosive environment. A fatigue crack can initiate and propagate under the influence of the crack-opening stress and the environment. The characteristic fatigue striations which can be found on the fracture surfaces are shown in Fig. 32. This 2024-T3 sample was fatigued in dry air.^[25] Similar striations may sometimes be found on corrosion fatigued

Fig. 32 Characteristic fatigue striations found on the fracture face of 2024-T3 fatigued in dry air^[25]

Source: With permission from ASTM.

samples, but often the subsequent crevice corrosion in the narrow fatigue crack dissolves them. Figure 33 illustrates that the crack growth per cycle depends on the stress concentration, ΔK , and the environment. The cracks in alloy 7075 and 2024 grow fastest in NaCl solution, and slowest in a vacuum.^[26] Figure 34 demonstrates that for a

Fig. 33 Fatigue cracks grow fastest in the NaCl solution, and slowest in a vacuum. The crack growth rate for in air is between the two extremes^[26]

Source: With permission from ASM International.

million cycles, high purity 7075-T6 alloy can withstand a stress of 270 MPa in a vacuum or in dry nitrogen, but can withstand only 180 MPa in humid air or humid nitrogen.^[27] The presence of water vapor decreases the fatigue life.

Every aluminum alloy is affected by corrosion fatigue. Figure 35 shows the ratio of fatigue strength (after 10^7 cycles) in air versus in 3% NaCl solution for alloys 5087-H34, 5086-H36, 6061-T6, 7075-T73, and 2024-T3.^[23] Alloy 6061-T6 had only 55% of the fatigue strength as in air, while alloy 2024-T3 had only 25% of the fatigue strength.

3.10 Filiform Corrosion

Filiform corrosion (also known as wormtrack corrosion) is a cosmetic problem for painted aluminium.^[28] Pinholes or defects in the paint from scratches or stone bruises can be the initiation site where corrosion begins with salt water pitting (Fig. 36). Filiform corrosion requires chlorides for initiation and both high humidity and chlorides for the propagation of the track. The propagation depends on where and how the alloy is used. Maximum rate of propagation occurs at 40°C and 85% relative humidity.^[29] Alloy 2036 was used for the engine hood of the Lincoln Towncar for over a decade without any incidence of filiform corrosion because of the hood's location. The heat from the engine keeps the relative humidity low, and the hood is not prone to scratches and chipping by stone bruising.

Figure 37 is a schematic showing the mechanism of filiform corrosion. The filament must be initiated by chlorides, and then it proceeds by a mechanism similar to

Fig. 35 The ratio of fatigue strength in air versus the fatigue strength in 3% NaCl solution, after 10^7 cycles^[23]
Source: With permission from ASM International.

crevice corrosion. The head is acidic, high in chlorides, and deaerated and is the anodic site. Oxygen and water vapor diffuse through the filiform tail, and drive the cathodic reaction. Filiform corrosion can be prevented by sealing defects with paint or wax, and keeping the relative humidity low.

Fig. 36 Filiform corrosion on clear coated aluminum. The filiform track initiates at a break in the coating (the scribe line) and wanders across the surface

Fig. 37 A cross-section of the filiform corrosion head illustrates that it is actually a type of crevice corrosion under a coating

Microbiological Induced Corrosion

Microbiological Induced Corrosion (MIC) applies to a corrosive situation which is caused or aggravated by the biological organisms. A classic case of MIC is the growth of fungus at the water/fuel interface in aluminum aircraft fuel tanks.^[30] The fungus consumes the high octane fuel, and excretes an acid which attacks and pits the aluminum fuel tank and causes leaking. The solution for this problem is to control the fuel quality and prevent water from entering or remaining in the fuel tanks. If fuel quality control is not feasible, then fungicides are sometimes added to the aircraft fuel.

CORROSION PREVENTION

In the previous section, the forms of aluminum corrosion and a few selected methods for corrosion prevention were discussed. This section describes the general methods for corrosion prevention of aluminum alloys.

Alloy Selection

The design stage is one of the most critical stages for corrosion prevention. A dominant factor is the specification of alloy and temper (heat treatment). Alloys with good corrosion resistance are the 1000 series, the 3000 series (in particular 3003 and 3004), the 5000 series with less than 3% Mg, and the 6000 series alloys, in particular 6061 which contains Mn. Alloy 6063 (without Mn) shows poorer corrosion resistance so the Mn appears beneficial. Alloys which have poorer corrosion resistance (although higher strength) are the 2000 series, the 5000 series with > 3% Mg, and the 7000 series which contain Cu in addition to the Zn (e.g. 7075). A very large factor in corrosion resistance is the effect of temper and presence of second phase particles. The Fe inclusions reduce the corrosion resistance by acting as pitting initiation sites. Copper precipitates in the 2000 alloys are also detrimental since these Cu containing particles also act as cathodic sites for oxygen reduction. For the 5000 series alloys with greater than 3% Mg, heat treatment can precipitate MgAl continuous precipitates along the grain boundaries. These continuous MgAl precipitates can dissolve preferentially, causing to IG attack or exfoliation.

Product Design

The second factor to be considered during the design stage is the shape of the final product. The design should provide water runoff (no standing water) without crevices or sharp corners where the coating can be damaged. Figure 38 illustrates different designs to avoid liquid entrapment.^[2] The designer should also avoid dissimilar metal contact and provide for the sealing of all fasteners, rivets and crevices.

Fig. 38 Designs and construction should be done to avoid liquid entrapment and corrosion^[2]

Source: With permission from ASM International.

Welds and Heat Affected Zones (HAZ)

Welded joints are a weak spot for many aluminum alloys. It is not possible to weld many aluminum alloys such as the 2024 and the 7075 due to phase segregation and cracking. For other alloys the heat affected zone (HAZ) is particularly problem-prone due to the precipitation of second phases. The HAZ is the zone between the weld metal and the unaffected base metal, where the metal has been heated, but not melted. This heating has led to the precipitation of many second phases along the grain boundaries and the corresponding depleted zone adjacent to the grain boundaries. This HAZ is prone to intergranular corrosion.

To prevent preferential dissolution of the weld metal, the weld metal should be slightly more noble than the base alloy. Hatch^[2] provides extensive tables for weld metal specifications.

Regular Maintenance

The aging aircraft program has demonstrated that an aircraft must be maintained adequately or the plane will be lost to corrosion. If the plane is carefully maintained, then its service life can be indefinite. Maintenance consists of inspecting for corrosion damage, and repairing the damage before the problem gets significant. The commercial airlines dismantle and inspect the aircraft during the “D-Check”.^[31] Unpublished tests reported that a bare aluminum panels which were wiped with #00 steel wool and automotive wax on a regular basis maintained its shine for over ten years of semi-industrial outdoor exposure.^[15]

Coatings

Coatings are a standard method of protecting an aluminum structure against corrosion. (The old corrosion prevention adage, “Paint it!” is valid.) Polymers, (e.g. acrylic or polyurethane) are commonly used for the top coat. However the problem is keeping the polymer attached to the aluminum base metal. For this reason, a good coating usually consists of multiple layers, each with their own particular function. The initial coating on the bare aluminum is a primer or a conversion coating. The function of the primer is to chemically react with the base metal to form a rough surface layer with which the polymer coating can bond chemically and mechanically. Chromate conversion coats such as Alodine were used in the past, but these are being replaced by non-chromate conversion coats. The automotive industry uses zinc phosphate conversion coats because it works for both steel and aluminum body sheet. For use with aluminum, the zinc phosphate bath must contain fluorides in order to precipitate the dissolved aluminum which can poison the reaction.

Anodizing

Other types of conversion coating are anodizing and the electrocoat (E-coat). The science of anodizing has been covered by many authors (Wernick,^[32]). In anodizing, the aluminum is immersed in an electrolyte (phosphoric acid, borate-boric buffer solution, sulfuric acid, oxalic acid, or chromic acid) and an anodic voltage is applied to the aluminum part. The aluminum reacts and grows a thick anodic oxide on the surface which consists of a barrier layer and a porous layer (Fig. 39). The porous layer can be colored with dyes and sealed by boiling in water to close the pores with aluminum hydroxide. The electrocoat is a rapid form of anodizing and polymer coating simultaneously. The E-coat is sprayed on to the positively charged aluminum, and the anodized layer is grown with the E-coat polymer.

Fig. 39 Cross-section of porous anodized aluminum^[3]
Source: With permission from Alcoa.

Another form of anodizing has been reported by Kuznetsova et al.^[33] The group exposed pure aluminum in a vacuum to water vapor, and then to an electron beam at 100 V and the resulting oxide was thin but highly resistant to corrosion.

Alcladding

Alcladding is the term which first described the cladding of 2024-T3 aircraft fuselage skin with a commercial purity aluminum sheet. Alloy 2024-T3 contains 4% Cu, which age-hardens and forms Al_2Cu precipitates, which provide strength, but deteriorate the corrosion resistance. To prevent the high corrosion rate, 2024 is clad with pure aluminum, which is galvanically more anodic than the copper containing alloy (see Table 1), and so it sacrificially corrodes and protects the 2024 base alloy, Fig. 40.^[34]

Fig. 40 Alcladding sacrificially protects the underlying metal^[34]

Source: With permission from MIT Press.

The alcladding is produced by hot rolling thin aluminum sheets on to the top and bottom of the 2024-T3 sheet. This aluminum sandwich is reduced in thickness, and the oxide film breaks, allowing nascent aluminum to meet and form a metallurgical bond. The pure aluminum outer layer has a more negative corrosion potential than the 2024-T3, so it acts as a sacrificial anode, preferentially corroding and protecting the 2024. This sacrificial protection is seen in Fig. 40.^[34]

The alcladding process is limited to sheet products, however a new electroplating process has been developed in which all shapes of aluminum products, forgings and machined screws, can be plated with pure aluminum, Fig. 41. This electroplating process uses an electrolyte of aluminum alkyls and metal fluorides dissolved in toluene at 90–100°C in an inert atmosphere.^[35] As long as the base metal is more noble than the plating aluminum, then the plated pure aluminum will protect the base alloy from corrosion by acting as a sacrificial anode. The base metal can be an aluminum alloy, or any metal (steel or copper) which is more noble than the pure aluminum (see Fig. 13 and Table 1) In aerospace applications, plating the steel fasteners with pure aluminum can prevent galvanic corrosion of aluminum structural members.

Corrosion Inhibitors

Corrosion inhibitors are defined as any substance which when added in small concentrations to the corrosive electrolyte, lowers the corrosion rate of the metal. Chromates, silicates, polyphosphonates and soluble oils are common inhibitors for aluminum.^[36] Chromates (containing hexavalent chromium) however are now known to be carcinogens and are being phased out of use. Inhibitors for mixed metal systems contain combinations of polyphosphonates, nitrites, nitrates, borates, silicates,

Fig. 41 Electroplating aluminum from a toluene solution can coat all shapes of aluminum products, forgings and machined screws^[35]

Source: With permission from ASM International.

and mercaptobenzothiazole.^[36] One of the most complete references for corrosion inhibitors for aluminum is, “Korrosions-Inhibitoren für Aluminium, Blei, Kupfer, und Zink,” by Witt.^[37]

Cathodic Protection

Aluminum may be cathodically protected by applying a negative voltage. The window of protection is very narrow; a slight voltage will protect, but a voltage more negative than -1.2 V versus the copper sulfate electrode will cause a large amount of hydrogen evolution which will form an alkaline atmosphere which dissolves aluminum. Cathodic polarization may be accomplished in soil by connecting a sacrificial zinc anode to the aluminum pipe or structure. The corrosion of the zinc imposes a slight negative potential on the aluminum and prevents it from corroding. Magnesium anodes are normally not recommended because they would apply a larger negative potential (-1.5 V) and cause caustic attack of the aluminum pipe. However magnesium anodes have been used in flowing irrigation systems and fish hatcheries since the alkaline atmosphere is continually swept away.

Sputter Deposited Aluminum

A recent development is the “stainless or sputter deposited Aluminum Alloys containing Mo, Ta, Cr, or W.”^[38] A potentiodynamic polarization is shown in Fig. 42. The potential required for pitting of these alloys is very high. These new alloys are not feasible via ingot metallurgy, but should have many applications in electronic circuits and thin films where corrosion resistance is required but bulk size is not.

Fig. 42 “Stainless aluminum” can be sputter deposited using aluminum and other elements^[38]

The Ideal Corrosion Resistant Aluminum Alloy

The ideal corrosion resistant aluminum alloy would be single phase and homogenous. However, strengthening of aluminum requires second phases for grain boundary pinning, and precipitation hardening. Therefore the ideal aluminum alloy would contain inert, insulating, second phase particles (e.g. aluminum oxide) to avoid galvanic corrosion problems.

CORROSION TEST METHODS

Introduction to Test Methods

Corrosion tests are necessary in order to predict the service life of an aluminum alloy or product in a given environment. However, it is often difficult to design a correct corrosion test, and to correctly interpret the results. Every metal will corrode somewhere, especially when given sufficient time. The choice of the correct corrosion test depends on service environment where the aluminum product will operate. For example, an aluminum automobile wheel will be subjected to corrosion and cyclic fatigue in all four seasons, ranging from the humid and hot summer drive to the beach, to the salt saturated slushy snow spray on the city streets in the winter. How does one choose a corrosion test to evaluate the aluminum wheel in this service environment? Because of the complexity of service environments, numerous corrosion tests have been designed. Below is a brief review of the common tests for aluminum alloys and products. The author recommends using triplicate samples in triplicate tests before making any decision which carries a significant economic price tag. Making an important alloy decision based on the result of one or two samples tested with one method is inviting disaster.

Exposure Tests

The Alternate Immersion (ASTM G44)^[17] is a cyclic test with the aluminum samples hourly immersed in 3.5% NaCl solution (10 mins) and then drying in air (50 mins). This cycle continues for 24 hr a day for 20-90 days. The American Society for the Testing of Materials (ASTM) has an extensive series of corrosion tests for aluminum alloys. Because aluminum is most susceptible to chloride pitting, the ASTM tests generally include some form of saltwater.

The classic corrosion test is the salt spray test in the saltwater fog cabinet, ASTM B117.^[17] The Saltwater Fog consists of leaving the sample continuously exposed to a mist or spray of saltwater for up to six weeks. This test imitates the conditions near a beach or in an automobile wheel well, and is used commonly for painted panels.

This is an ideal test if the customer plans to use the aluminum product in a saltwater fog, but this does not necessarily correlate to any other environments. For example, filiform corrosion can initiate in the saltwater spray, but it does not propagate under the spray because of the 100% humidity.

Seacoast exposure is conducted by exposing the samples on open-air racks within sea-spray range of the ocean. The Aluminum Company of America (Alcoa) operates a seacoast exposure site at Point Judith, Rhode Island. The LaQue Center for Corrosion Technology has a commercial seacoast exposure site in North Carolina.

Colvin et al.^[38b] reported that for accelerated corrosion tests of aluminum with automotive coatings, that a HCl dip test correlated well with seacoast exposure, while the Dry Bottom MASTMASSIS (ASTM G85^[17]) correlated well with highway underbody exposure. They reported that the saltspray ASTM B117^[17] did not correlate well to either seacoast nor highway exposure.

A humidity cabinet can be used to propagate filiform corrosion. Maximum growth occurs at a relative humidity of 80% and a temperature of 40°C, however the initiation must be initiated with chlorides, either with a saltwater spray, or by holding over HCl acid.^[29]

The intergranular corrosion test (ASTM G10)^[17] uses the same NaCl-H₂O₂ solution as the ASTM G69, however after 2 hr of immersion, the aluminum sample is removed from the test, cleaned and cross-sectioned and polished to reveal the mode of corrosion attack, either pitting alone, or pitting and intergranular corrosion. This test is useful for revealing the presence of sensitized grain boundaries susceptible to intergranular corrosion.

The EXCO test (ASTM G34)^[17] is an immersion test which accelerates the exfoliation of susceptible aluminum alloys. The ASTM G34 test consists of a 5-72 hr immersion in a solution containing sodium chloride, potassium nitrate, and nitric acid at room temperature. Typical EXCO results are shown in Fig. 43.^[17]

Fig. 43 Typical EXCO results^[17]

Source: With permission from ASTM.

Electrochemical Tests

The alloy composition or temper can be approximated by the aluminum alloy's corrosion potential measured by the ASTM G69.^[17] For this test, the aluminum sample is cleaned and then immersed in IM NaCl, with 9 ml of 30% hydrogen peroxide (H_2O_2) per liter of solution for 1 hr. The corrosion potential is the average open circuit potential recorded for the last half hour versus the saturated calomel electrode (SCE). The corrosion potential may be compared to the values shown in Table 1.

Potentiodynamic polarizations (ASTM G5)^[17] may be used to understand the corrosion mechanisms of an aluminum alloy. Figure 44 shows the potentiodynamic polarization of 99.999% pure aluminum (dotted line) versus alloy 2024-T3 (solid line) in a 3.5% NaCl solution saturated with air. The sample surfaces were wet polished with distilled water and 600 grit SiC paper prior to testing, which caused the natural formation of an oxide-hydroxide surface film. The scan rate was 1 mV/sec, starting at -900 mV versus SCE. The cathodic reaction, oxygen reduction (Eq. 3) occurs to the left and the anodic reaction, aluminum oxidation, occurs to the right. The pure aluminum exhibits a cathodic current approximately ten times lower than the cathodic current on the 2024-T3 because there are very few second phases which break through the film and provide an electrical path for the electrons. The high currents for the 2024-T3 in the anodic region indicate a high rate of pitting corrosion. The pure aluminum did not show pitting but stayed passive because there were no breaks in the passive film which would allow the chloride ion ingress. By extrapolating the cathodic and anodic currents to their intersection, one may estimate the corrosion rate of each system. The 2024-T3 exhibits a corrosion rate of about $10\text{ }\mu\text{A}/\text{cm}^2$, while the corrosion rate of the pure aluminum is closer to $0.1\text{ }\mu\text{A}/\text{cm}^2$.

Fig. 44 Potentiodynamic polarization of pure Al and alloy 2024-T3 in 3.5% NaCl solution

Electrochemical Impedance Spectroscopy (EIS) is a non-destructive method which can be used to look for pinholes or defects in coatings on aluminum^[39] or measure the thickness of coatings or anodized layers.^[40] An EIS test is performed by passing a small sine wave voltage ($\pm 5\text{ mV}$) through an immersed sample and measuring the resulting current. The AC resistance of a system is called the impedance, $|Z|$. The lag between the maximum current and the maximum voltage is known as the phase shift, θ . These parameters, the phase shift, θ , and the impedance, $|Z|$, generated from EIS testing may be used to estimate the film quality and thickness. The part of the curve that gives the most information about the quality of the layer lies at a low frequency, 0.1 Hertz. The data at 0.1 Hz can show the presence of pinholes in the coating by a flattening of the impedance or a decreasing phase angle. The quality of the coating is maximized at the point where the impedance, $|Z|$, and the phase shift, θ , are at their maximum. A plot of $\log(f)$ versus $\log |Z|$ can be interpreted to provide the coating thickness and the average corrosion rate under the coating. The thickness of the coating can also be estimated from the capacitance of the coating by approximating the layer as a parallel plate capacitor at frequencies where the phase angle approaches -90° . With this approximation the following equation can be utilized in order to determine the thickness of the oxide layer:^[40]

$$d = \epsilon_i \epsilon_0 A 2\pi f (Z - Z_0) \quad (\text{parallel plate capacitor}) \quad (10)$$

where d = thickness of the layer, ϵ_i = dielectric constant of the layer, $\epsilon_0 = 8.854 \times 10^{-12}\text{ F/m}$ (dielectric of free space), A = surface area (cm^2), f = frequency (Hz), Z = impedance (Ω) at frequency f , and Z_0 = impedance at high frequency (a.k.a. solution resistance). Typical EIS results are shown in Fig. 45 for coated aluminum, in which the coatings are ranked from the best to the worst, from the top to the bottom. The impedance $|Z|$ for triplicate coated aluminum cans is shown as the solid circles. The phase angle is shown as the open squares. The impedance shows almost linear behavior after two years of storing chicken noodle soup and pet food, but a decrease in the impedance, and in the coating quality, after storing sauerkraut in similar coated cans for the same period. The phase angle drops from -90° for the two top curves, to smaller values, also indicating a change from capacitive behavior to resistive behavior.

For additional information on corrosion tests for aluminum, a recent review article has been written by Lifka.^[41] Additional reviews on the corrosion of aluminum alloys may be found in the *ASM Handbook*, Vol. 13,^[23] in *Aluminum*, edited by J. E. Hatch,^[2] and in the *Corrosion Handbook*.^[42]

SUMMARY

Aluminum alloys will provide indefinite service life in certain environments, such as at room temperature in air or in a neutral aqueous solutions free from chlorides. In these benign environments, aluminum forms a protective oxide/hydroxide film on its surface which prevents further corrosion. However, in acidic, or caustic environments, aluminum can corrode. Additionally in neutral pH aqueous solutions which contain oxygen and chlorides, aluminum will corrode due to the formation of acidic occluded cells. However, with careful design, careful choice of alloys, coatings and maintenance, aluminum can provide a long and indefinite service life.

Abstract

This entry provides a comparative study on the corrosion protection efficiency of Ce, La films as well as Ce/La- and La/Ce-bilayered coatings deposited onto AA7075 and AA6061 substrates by the radio frequency magnetron sputtering technique. The coating thickness ranged from ~12 to 835 nm, which changed with the deposition parameters and substrate composition. The relationship between microstructure, roughness, and electrochemical performance is examined. The reactivity and crystallinity of rare earth (RE) films can be tailored by adjusting the sputtering parameters. Sputtered La films with a thickness of ~390 nm and an average roughness of 66 nm showed the best corrosion protection properties in chloride medium as determined by potentiodynamic curves and electrochemical impedance spectroscopy. The method to obtain RE-bilayered coatings, i.e., La/Ce or Ce/La as well as the substrate composition and applied power, conditioned their inhibition properties. The RE-bilayered coatings displayed better barrier properties than Ce films, which were worse than those featured by La films.

Keywords: Bilayer; CeO_2 ; Cerium oxide; Corrosion; La_2O_3 ; Lanthanum oxide; Magnetron sputtering; Rare earth; Thin film.

INTRODUCTION

Rare earth (RE)-based technology has been extensively investigated as a replacement of chromate conversion coatings for both corrosion protection and pretreatments prior to painting different metallic substrates.^[1–5] Among them, aluminum alloys for aircraft industry require effective environmentally friendly inhibitors to prevent pitting corrosion.^[6] Cerium and lanthanum salts are the most common coatings used to inhibit the corrosion on aluminum alloys.

The corrosion pathway of these lanthanides has also been widely discussed, and it is associated with the cathodic areas blocked by precipitation of a film of lanthanide oxide/hydroxide,^[7–10] but it strongly depends on the metallic substrate. Additionally, a variety of approaches enable the deposition of metallic coatings containing RE elements for corrosion protection.^[11–25] However, some limitations of RE coatings obtained by conventional methods are as follows: (i) the precipitation of an insoluble protective RE oxide/hydroxide layer that produces coatings with irregular characteristics and (ii) the presence of cracks that

can penetrate the entire cross section of the layer. These cracks represent preferential pathways to attack the substrate by aggressive corrosive species.^[26] Radio frequency (RF) magnetron sputtering is one of the most physical approaches used to obtain thin films and could be favorable for fabricating coatings on large scale because of their uniformity, easy fabrication, adhesion, and control parameters.^[27] Changes in growth, morphology, and/or chemical composition of the films to produce valuable properties can also be modulated using RF magnetron sputtering.^[28–30]

Undoubtedly, with the rapid development of the aerospace industry, reducing weights, increasing reliability, stability, and proper option of structured materials have become more vital for the success of advanced designs. In this way, considering that RF magnetron sputtering is a scarcely explored technique for inhibiting the corrosion of metallic substrates,^[26,31–35] it can be an alternative to search new methods to protect metallic substrates for industrial applications. This entry was aimed at using the RF magnetron sputtering technique to evaluate the inhibition efficiency (IE) of Ce, La films, and bilayered coatings (Ce/La and La/Ce) in order to delay the pitting corrosion

of AA7075 and AA6061 aluminum alloys. Due to the microstructure (including chemical composition) of REs coatings, it is fundamental to understand the role played by REs as corrosion inhibitors and thus prepare effective RE-containing inhibitors once the dependence on microstructural and corrosion properties has been investigated. To characterize properly the structure, morphology, topography, and chemical composition of the sputtered coatings, samples were also deposited on glass and silicon (100) substrates.

EXPERIMENTAL

Coating Deposition

Single and bilayered RE coatings were deposited by RF (13.56 MHz) magnetron sputtering in a homemade system onto AA7075 and AA6061 aluminum alloy substrates. The targets were 50.8 mm diameter CeO_2 and La_2O_3 disks (Plasmaterials Company) with purity of 99.99%. The targets were bound to copper backing plates to avoid rapid degradation and enhance the thermal conductivity. The system was evacuated by means of a rotatory and turbo pump to attain a residual pressure below 8×10^{-4} Pa. Before the deposition stage, 60 min in an etch chamber and insertion of samples with the concomitant preheating were performed under argon plasma. The working pressure was 0.266 Pa, and the distance between the magnetron guns and the samples was 60 mm. The discharge powers (P) for the RE thin films were set at 60 and 90 W, varying the temperature ($T = 80^\circ\text{C}$ and 200°C) and deposition time ($t = 25, 40$, and 60 min). As for the RE-bilayered coatings, the synthesis was carried out at 60 W for La and 80 W for Ce, using a temperature of 80°C and 60 min. The synthesis was carried out under ultrahigh-purity Ar atmosphere with a gas flow of 30 sccm.

An as-received aluminum alloy AA7075 sheet (0.06 cm thick) was cut into 2×2 cm substrates, whereas as-obtained AA6061 bar was sliced into disks (2.5 cm in diameter and 0.2 cm thick). The coatings were simultaneously deposited onto glass and silicon (100) substrates, which were chosen for characterization purposes. Prior to deposition, the substrate surfaces were finely abraded using 1,000, 1,500, and 2,000 grade SiC paper; cleaned by rinsing with deionized water; and finally sonicated in isopropyl alcohol and deionized water for 20 min, respectively.

Characterization of samples

The phase composition and crystal structure of the as-synthesized films were determined by powder X-ray diffraction (XRD) using an Advanced Bruker D8 diffractometer, with Cu K_α radiation at 35 kV and 25 mA, and at a scan rate of 0.021 min^{-1} . Film morphology was examined by scanning electron microscopy (SEM) using a JEOL JSM 7600F.

The topography and roughness were measured and analyzed by AFM, Veeco, Model diMultiMode V, and controller diNanoScope V with cantilever RTESP tips. The obtained data were analyzed using the NanoScope® III ver. 5.12r3 software.

The chemical composition of the bilayered films was characterized by X-ray photoelectron spectroscopy (XPS) measurements using a Thermo Fisher-VG system equipped with a dual X-ray source (Al-Mg) as well as hemispherical electron analyzer with seven channeltrons. In the experiments, the Al K_α (1486.7 eV) source at 100 W was used. The data acquisition was carried out using a pressure of 7×10^{-10} torr in the analysis chamber, and the resolution of the peaks was optimized using a pass energy of 0.15 eV. The obtained data were analyzed using the SDP® v4.1 software.

Electrochemical Performance

The corrosion behavior of coated and uncoated aluminum alloys was analyzed by open-circuit potential (E_{ocp}), polarization resistance (R_p), potentiodynamic polarization, and electrochemical impedance spectroscopy (EIS) measurements using a 3.0 wt% NaCl solution as a corrosive medium. A potentiostat/galvanostat (Gamry 600 series) was used with a conventional experimental setup of a three-electrode cell. A graphite bar (counter electrode) and a saturated calomel electrode (SCE, reference electrode) were employed to perform the corrosion experiments. The working electrode had an exposed area of 0.126 cm^2 . Polarization resistance measurements were conducted from 20 mV vs SCE (cathodic) to 20 mV vs SCE (anodic) of corrosion potential at a sweep rate of 0.5 mV s^{-1} . To evaluate the susceptibility of the surface of the samples to pitting corrosion and to obtain information about the corrosion rate and corrosion potential, potentiodynamic polarization curves were scanned. These curves were measured from cathodic to anodic areas from -250 mV vs SCE (E_{ocp}) to 1000 mV vs SCE at a sweep rate of 0.5 mV s^{-1} . EIS measurements were carried out from the frequency region of 10^5 – 0.01 Hz (10 frequency points per decade) with amplitude of mV rms. At least three replications were used for every corrosion-rate measurement.

RESULT AND DISCUSSION

Influence of Process Parameters on CeO_2 and La_2O_3 Coatings

To study the effects of power (P), substrate temperature (T), and deposition time (t) on the film composition and corrosion behavior, two sets of experiments were carried out. The first series of experiments was done maintaining a constant value of two variables and so on up to obtain a complete study of the influence of the deposition

parameters. Other deposition parameters were also kept constant: 20 m torr vacuum pressures, substrate-to-target (ds-t) fixed at 6 cm and 30 sccm of argon. The second set of experiments was realized taking into account the best deposition parameters to produce $\text{CeO}_2/\text{La}_2\text{O}_3$ and $\text{La}_2\text{O}_3/\text{CeO}_2$ bilayers coatings on both aluminum alloys and glass or silicon substrates for convenient characterization. Consequently, the diverse experiments are discussed in terms of the effect that the operating conditions have on the morphology, thickness, and/or electrochemical behavior of the CeO_2 and La_2O_3 coatings deposited by RF magnetron sputtering on the AA6061 and AA7075 aluminum alloy.

Structural analysis of Sputtered Ce and La Coatings

Figure 1a–d shows XRD patterns of the sputtered deposited RE coatings at different deposition parameters on glass substrates. In general, the spectra show a typical amorphous signal at low angles, $\sim 12^\circ$ (2θ – 20°). The amorphous peak of the glass substrate diminished as the obtained thickness increased depending on the deposition conditions. According to the PDF 40-1281 and PDF 36-1481 standards, the prevailing peaks are related to the composition of La_2O_3 and $\text{La}(\text{OH})_3$ with a hexagonal structure (Fig. 1a and b); however, small La_2O_3 peaks (PDF 48-1113) can also be observed in the spectra. It is evident that on standardized scales, the crystalline structure of the samples presented important changes depending on the

deposition parameters; such differences are particularly observed at the (100), (002), (10–1), and (110) planes of La_2O_3 and at the (100), (110), (101), (200), (201), and (300) planes of $\text{La}(\text{OH})_3$.

Kakushima et al.^[36] have reported that the transformation of La_2O_3 into $\text{La}(\text{OH})_3$ or carbonates occurred when La_2O_3 coatings were exposed to the atmosphere and in our case, due to the proposed applications of these coatings, it was not exposed to special atmosphere after obtaining the sputtered coatings, whereby hydroxide and small carbonate signals were detected. The $\text{La}(\text{OH})_3/\text{La}_2\text{O}_3$ formation is favored with the variation of crystal size, which in turn depends on the substrate temperature and deposition time ($P_{60}T_{200}t_{25}$), i.e., the broadening of the main peaks is observed with the deposition time. The decrease in crystallite size is also favored by the increasing power (90 W) (Fig. 1b). The reactivity of La_2O_3 to form $\text{La}(\text{OH})_3/\text{La}_2\text{O}_3$ films is also inhibited with the power. Additionally, XRD patterns of La coatings fabricated at $P_{90}T_{80}t_{60}$ indicate a preferential growth at the (100) plane. These results suggest that the deposition parameters can be modulated substantially to influence the final film microstructure.

A magnification in the 20° – 60° range (2θ – 20°) was performed in the as-prepared samples in order to observe and corroborate in detail crystallinity changes and hydroxide/carbonate formation with the deposition parameters (Fig. 2a–l). The XRD of these samples confirmed that the crystallinity and the $\text{La}(\text{OH})_3/\text{La}_2\text{O}_3$ formation are quite dependent on the sputtered conditions. These results

Fig. 1 XRD patterns of sputtered lanthanum and cerium coatings on glass substrates by varying the power (60 and 90 W), deposition time (25, 40, and 60 min), and substrate temperatures (80°C and 200°C)

seem to be in agreement with previous works,^[37,38] where it has been found that the crystallite size is reduced with the increasing power and deposition time, although it is also obvious that lattice strain, dislocations and grain boundaries, or even instrumental contributions can contribute to the signal broadening. The crystallite size under the different experimental conditions was determined using Scherrer equation for each peak regarding each RE coating.^[39]

In this equation, k is the Scherrer constant (0.9 for sphere crystallites), λ is the X-ray wavelength (0.15418 nm), hkl is the *full width at half medium*_(hkl) in radians of XRD peak, and hkl is the Bragg angle. The pseudo-Voigt profile function was used to determine the full-width and

half-maximum broadening, considering symmetrical peaks for the fitting.^[40–42] The crystallite sizes for lanthanum specimens varied from ~0.9 to 12.8 nm with a film thickness ranging from ~269.5 to 390.2 nm (60 W) and from ~499.0 to 835.5 nm (90 W), confirming the trend to diminish the crystallite size with the process parameters (Table 1).

On the other hand, Fig. 1c and d shows the XRD pattern of Ce coatings from which it can be observed that independently of the substrate temperature and deposition time, preferred signals were detected from the (111) plane at 60 W. The growth of this orientation was more pronounced at high deposition time (60 min) and substrate temperature (200°C). By increasing the power (to 90 W), the coating exhibited a weak intensity of the fluorite cubic CeO₂ structure at the (111) plane at about 28.52° (PDF 34-0394). Ce films produced at 90 W showed amorphous films, whereas at 60 W, only at high temperature, oriented films were observed. The widening of peaks caused a small

displacement in the (111) plane toward low diffraction angles, which can be correlated with the lattice expansion; during the Ce film formation, the Ce³⁺ and Ce⁴⁺ fractions can coexist, provoking a lattice deformation at the same time that the crystallite size decreased. In this case, the crystallite size forming crystalline films ranged from 1.1 to 7.0 nm, with film thicknesses of 12.7–40.1 nm (60 W) and 42.2–158.1 nm (90 W).

The increase in thickness is closely related to the RF power density, which can be explained in terms of bombarding argon ions, i.e., the ceramic target with high energy at high-target bias voltage, temperature, and deposition time.

Figure 3a–d shows XPS spectra of representative RE samples deposited on aluminum alloys (AA6061 and AA7075) for La3d and Ce3d core levels with their corresponding O1s energy level.

The La3d core-level spectra of lanthanum compounds show their well-known splits into 3d_{5/2} and 3d_{3/2}

components (due to a spin-orbit interaction) with their characteristic doublet (Fig. 3a). The peaks at 853.48 and 836.71 eV matched well with La³⁺ species. The corresponding satellite peaks are observed at 857.97 and 841.17 eV, respectively, with a separation of the main peak of $\Delta E \approx 4$ eV.^[43]

The O1s level spectra can be deconvoluted into two main peaks located at 532.01 and 534.45 eV, which are correlated with lanthanum oxide/hydroxide compounds, even the peak at ~534 eV could indicate the presence of La₂O₂CO₃ (Fig. 3b). The oxide/hydroxide ratio varied from 0.62 to 0.81 due to the well-known hygroscopic properties.^[43,44] The chemical environment around the O atoms indicates that under the synthesis parameters, the obtained films are free of contamination or foreign compounds such as La₂O₂CO₃; however, the lanthanum hydroxides or carbonates could be readily formed when the film is exposed to the atmosphere.

On the other hand, Fig. 3c and d displays the Ce3d_{3/2,5/2} spectra are composed of two multiplets that correspond to the spin-orbit 3d_{5/2} and 3d_{3/2} core holes, which in turn are associated with the presence of both Ce³⁺ and Ce⁴⁺ valence states ($\Delta E \approx 18$ eV).^[45] The Ce⁴⁺/Ce³⁺ was calculated by solving the following expressions: $\%Ce_2O_3 = \frac{Ce^{3+}}{Ce^{3+} + Ce^{4+}}$; $\%CeO_2 = 1 - \%Ce_2O_3$, and its value varied from 0.97 to 2.84 depending on the deposition parameters.^[46]

Two features can be highlighted in this analysis. First, the deconvoluted spectra show that both Ce⁴⁺ and Ce³⁺ chemical states form the sputtered coating films, although Ce⁴⁺ species predominate. Second, the XPS results confirmed the formation of both Ce⁴⁺ and Ce³⁺ species during the sputtering process, but the XRD peaks corresponding to the crystalline Ce₂O₃ hexagonal phase were missing; thus, in agreement with a previous work, it can be suggested that Ce³⁺ species may exist as Ce₂O₃ in an amorphous phase or around oxygen vacancies in CeO₂.^[47,48] O1s XPS spectra have been a useful tool to differentiate molecular water from hydroxyl dissociated groups on the surface of ceria compounds (Fig. 3d). The three features in our spectra located at 530.06, 530.94, and 532.66 eV have been assigned to lattice oxygen, hydroxyl groups, and adsorbed water, respectively.^[49]

Figure 4a–x shows a representative set of AFM images from sputtered cerium and lanthanum oxide deposited on AA6061 substrates, as well as the AFM images for metallic substrates. In general, the initial stages for the sputtered layer buildup were observed as a rapid deposition on the surface in the form of islands of different sizes; as the deposition time was increased, the initial islands grew and merged to produce a thin film that covered the entire substrate. The lanthanum coatings show agglomerates forming the film, which vary from 50 to 300 nm in diameter with a height of ~20–55 nm. Unfortunately, a clear trend cannot be observed in the topography of La oxide coatings with the deposition parameters, and consequently,

no trend can be mentioned in the R_a values. For comparison with the substrate, the R_a reduces with the RE films (196.6 nm). Similar results were obtained with the cerium coatings; although in this case, they possessed rougher surfaces with R_a values that ranged from 12.7 to 289.1 nm.

The micro-defects observed in the AFM images occurred when energetic ions were accelerated by the voltage discharged toward the substrate, which induced the re-sputtering at the growing coating surface, explaining the rougher surface of the Ce coatings in comparison with films deposited on La targets at similar deposition parameters.

Micrographs of La and Ce films sputtered onto AA6061 substrates are shown in Figs. 5 and 6. The SEM images show typical RE growth of nanocrystalline coatings; in contrast with our previous reports, where a uniform and crack-free film was observed on the AA6061 aluminum alloy, some cracks are observed in the coatings.^[50] Micro-sized defects imply nucleation and island growth process; however, by increasing the coating thickness, the quantity and depth of these defects decreased due to island coalescence. The power and deposition time cause that the agglomerates forming the film change from fine to coarse with a film thickness that varies from 269.5 to 835.5 nm and from 19.3 to 158.1 nm for La₂O₃/La(OH)₃/La₂O₂CO₃ and CeO₂/Ce₂O₃ coatings, respectively.

Microstructural Analysis of Ce/La- and La/Ce-Bilayered Coatings

From the overall conditions and microstructural characterization of Ce and La layers, Ce/La- and La/Ce-bilayered coatings were produced at $P_{80}T_{80}t_{60}$ and $P_{60}T_{80}t_{60}$ on both aluminum alloy substrates. The AFM analysis of the as-obtained bilayered coatings with their corresponding height profile was analyzed and showed in Fig. 7. It is important to mention that the analysis considered other projections to confirm the height profile. In general, the bilayered coatings showed closed aggregates or domains with a separation between them of barely 20 nm and are ~130 nm in height. The average base roughness is clearly modified depending on the RE element that is deposited onto the metallic substrate; aluminum alloy/La/Ce and the RE layers were smoother than those observed in the aluminum alloy/Ce/La system (Table 1).

The domain distribution of the lanthanum films appears nonuniformly, and it seems that they tend to grow from the center to the edges. Macro-domains appear as bigger aggregates of polymorphic nanostructures in size and shape. The layer-by-layer growth mechanism of the mixed oxides shows a height from crest to valley of about 11 nm. The film growth was not modified by the order of the RE deposition and corresponds to a typical Stranski–Krastanov mechanism (Fig. 8).

The morphology of the bilayered samples is shown in Fig. 9a–j. SEM micrographs revealed a dense fine-grained

Fig. 3 Representative high-resolution XPS spectra of as-obtained samples at $P_{60}T_{80}t_{60}$: (a) La3d, (b) La O1s, (c) Ce3d, (d) Ce O1s, and (e) $\text{Ce}^{4+}/\text{Ce}^{3+}$ and La oxide/hydroxide ratios for each experimental parameter

morphology in all the systems deposited on both aluminum alloys. The morphology did not change with the order of deposited $\text{Ce}_{80\text{W}}/\text{La}_{60\text{W}}$ or $\text{La}_{60\text{W}}/\text{Ce}_{80\text{W}}$ layers, which grow from island up to covering the entire substrate surface with an average grain size of about 15 nm. The resulting coatings displayed film thicknesses of 268.6 nm (at deposition rate of Ce/La : 0.075 nm s^{-1}) and 284.3 nm (La/Ce : 0.079 nm s^{-1}) for AA6061 substrates, whereas the thicknesses of the AA7075 substrates were 182.1 nm (Ce/La : 0.050 nm s^{-1}) and 193.1 (La/Ce : 0.054 nm s^{-1}). The deposition rate was lower ($\sim 30\%$) when AA7075 was used as the substrate; this variation can be correlated with the composition and features of the oxide film formed on the substrate surface.

Generally, the mobility of atoms deposited on the substrate surface must have the adequate energy to be linked together, forming initial grains for island shape, and extended to the substrate.

Thus, the necessary conditions for favoring the growth of energetic atoms as stable grains and increasing the growth rate of the layer are favored with the AA6061 aluminum alloy.

In order to correlate the development of the bilayered microstructure with the coating thickness, XRD patterns of sputtered samples were analyzed on Si (100) substrates, and the spectra are shown in Fig. 10a and b. The XRD patterns show a combination of the RE oxide compounds with their respective structural phase. The average crystallite

Fig. 4 AFM images of sputtered RE films deposited onto AA6061 aluminum alloys using the evaluated deposition conditions

size for Ce/La coatings was ~16.84 nm, whereas La/Ce films show a crystallite size of ~2.9 nm. The crystallite size and roughness of bilayered coatings was slightly enhanced in comparison with monolayers.

Considering that the ion bombardment and temperature on the growing coating surface would induce compressive internal strain by causing atomic displacements and densification of the coating, the compressive strain associated with crystallite coalescence would be more evident during the substrate/La/Ce interaction.^[33]

ELECTROCHEMICAL MEASUREMENTS

Potentiodynamic Curves

It is known that during the corrosion test of aluminum, a faster generation of Al³⁺ at anode sites resulted in a reduction of the local pH, which promotes gas evolution. Hydrogen gas evolution can be used to position continuous localized corrosion.^[51,52] It is also important to note that small changes in the microstructure and/or in the

Fig. 5 High-resolution scanning electron microscopy (HRSEM) of La coatings on AA6061 aluminum alloy substrates: (a) $P_{60}T_{80}t_{25}$; (b) $P_{60}T_{80}t_{40}$; (c) $P_{60}T_{80}t_{60}$; (d) $P_{60}T_{200}t_{25}$; (e) $P_{60}T_{200}t_{40}$; (f) $P_{60}T_{200}t_{60}$; (g) $P_{90}T_{80}t_{25}$; (h) $P_{90}T_{80}t_{40}$; (i) $P_{90}T_{80}t_{60}$; (j) $P_{90}T_{200}t_{25}$; (k) $P_{90}T_{200}t_{40}$; (l) $P_{90}T_{200}t_{60}$

passivating Al_2O_3 film could be provoked during the sputtering of RE films at 80°C and 200°C. However, in this work, it was only analyzed the influence RE deposition parameters and the barrier properties that provided in aggressive media.^[53–55]

In order to assess the passivation behavior of coated AA7075 and AA6061 aluminum substrates, potentiodynamic tests were performed in a 3.0wt% NaCl solution. Potentiodynamic curves and derived kinetic parameters for La/Ce-bilayered coatings fabricated at $P_{80}T_{80}t_{60}$ and $P_{60}T_{80}t_{60}$ on both aluminum alloy substrates are shown in Fig. 11a and b. For comparison purposes, the electrochemical performance of individual Ce or La coatings, under similar deposition conditions, and bare substrates is also shown in the plot.

In general, the potentiodynamic curves showed a positive displacement shifting the corrosion potential (E_{corr}). The displacement of E_{corr} is because of the decrease or increase in the evolution rate of O_2 reduction and/or H_2 production and the increase in the passivation current density (i_{passive}). In the cathodic branch of both aluminum alloys, a region

of mixed kinetic control is seen, where the current density tends to reduce by modifying the charge transfer mechanism. The performance of RE coatings appeared totally different when the polarization curves were recorded on different metallic substrates, highlighting the influence of substrate composition and its microstructures on the electrochemical performance. From Fig. 11, it is clearly seen that the RE coatings can accelerate or decelerate the O_2 reduction/ H_2 evolution rate and decrease the i_{passive} value, and consequently shift E_{corr} depending on the metallic substrate used.

In the anodic branch, uncoated aluminum (AA6061 and AA7075) showed two typical regions. In the first region, the dissolution of the aluminum alloy occurs above its open-circuit potential because an active electrochemical reaction takes place on the surface and the anodic current increases rapidly from -863 to $-240 \text{ mV}_{\text{SCE}}$ and from -806 to $-90 \text{ mV}_{\text{SCE}}$ for AA6061 and AA7075, respectively (Table 2). In a subsequent step, there is a passivation region beginning at potentials of -90 and $-240 \text{ mV}_{\text{SCE}}$. Sputtered La, La/Ce, and Ce/La coatings on AA6061 showed a

Fig. 6 HRSEM of Ce coatings on AA6061 aluminum alloy substrates: (a) $P_{60}T_{80}t_{25}$; (b) $P_{60}T_{80}t_{40}$; (c) $P_{60}T_{80}t_{60}$; (d) $P_{60}T_{200}t_{25}$; (e) $P_{60}T_{200}t_{40}$; (f) $P_{60}T_{200}t_{60}$; (g) $P_{90}T_{80}t_{25}$; (h) $P_{90}T_{80}t_{40}$; (i) $P_{90}T_{80}t_{60}$; (j) $P_{90}T_{200}t_{25}$; (k) $P_{90}T_{200}t_{40}$; (l) $P_{90}T_{200}t_{60}$

tendency to form a passive stage with current densities of $1.65 \times 10^{-6} \text{ A cm}^{-2}$ ($-611 \text{ mV}_{\text{SCE}}$), $1.69 \times 10^{-5} \text{ A cm}^{-2}$ ($-540 \text{ mV}_{\text{SCE}}$), and $2.32 \times 10^{-7} \text{ A cm}^{-2}$ ($-850 \text{ mV}_{\text{SCE}}$), followed by a transpassive zone, whereas the other systems remained with the shape of bare aluminum.

On the other hand, Ce, La, Ce/La, and La/Ce coatings on AA7075 substrates showed similar shapes in the anodic and cathodic branches. As it can be seen, in all the cases, no passive behavior occurred. The corrosion potential of the samples is about $-740 \text{ mV}_{\text{SCE}}$ and does not show significant changes. The potential of coated samples is $\sim 70 \text{ mV}_{\text{SCE}}$ more positive than the uncoated substrate. In the anodic branch, a strong increase in the current density with the potential is observed, suggesting that even with coating, the samples have pits at discrete locations on the surface; thereafter, a tendency to the repassivation of micro-sized pits can be observed.^[56] It is known that during the growing process of an occluded pit, the concentration of metallic cations increases gradually due to the active dissolution within the pit.^[57–60] Once the saturated concentration is reached, a salt film will be formed at the bottom of the pit.

The dissolved metallic cations move outward through the salt film under the action of an electric field across the film. The stronger the field, the faster the metallic cations move through the film.

Hence, at this stage, the growth of the pit is controlled by the ohmic potential drop across the salt film. The absence of a passive plateau suggested a limited effect of the RE coatings on the inhibition of the anodic dissolution of AA7075. However, the corrosion potential shifting to positive potentials suggests a certain protection degree.

The observed differences in both substrates can be explained as follows: it is well known that microstructures developed in high-strength aluminum alloys such as AA7075 are complex and incorporate a combination of equilibrium and nonequilibrium phases. Typically, such alloys have a chemical composition incorporating up to ten alloying elements. Such elements primarily include Zn, Mg, and Cu; however, appreciable and specific amounts of Fe, Si, Cr, Ti, Zr, and Mn are often present (both as deliberate additions and as impurities). As for localized corrosion, the intermetallics of particular interest are those

Fig. 7 Representative 3-D images of sputtered bilayered films at 80°C and 60 min: (a) $\text{Ce}_{80\text{w}}/\text{La}_{60\text{w}}$ (AA6061); (b) $\text{Ce}_{80\text{w}}/\text{La}_{60\text{w}}$ (AA7075); (c) $\text{La}_{60\text{w}}/\text{Ce}_{80\text{w}}$ (AA6061); (d) $\text{La}_{60\text{w}}/\text{Ce}_{80\text{w}}$ (AA7075). The section analysis is also shown as a height profile

that appear at the highest proportion, either by size or by frequency. For AA7075, such particles have been identified (in random order) as Mg_2Si , MgZn_2 , $\text{Al}_7\text{Cu}_2\text{Fe}$, Al_2CuMg , Al_2Cu , and $\text{Al}_3\text{Fe}_{25}$.^[61–63] On the other hand, different precipitates have been identified in the AA6061 aluminum matrix such as Al_3Fe , α -(Fe, Cr, Mn) $_3\text{SiAl}_{12}$, β -(Fe, Cr, Mn) $_2\text{Si}_2\text{Al}_9$, Si , Mg_2Si , and π -(Fe, Cr, Mn) $\text{Mg}_3\text{Si}_6\text{Al}_8$. In this context, although several factors affect aluminum dissolution, the substrate composition conditioned the microstructure, which in turn plays an important role in enhancing the passivation in aluminum alloys.

Kinetic parameters and corrosion rate of the as-obtained samples are shown in Table 2. It is important to note that

only Tafel slopes with a physical significance were calculated and shown in this table. The presence of deposited REs provoked changes in the anodic Tafel slopes, which varied from 93.9 to 128.2 and 41.3 to 92.1 mV dec^{-1} , for AA6061 and AA7075, respectively. The lowest corrosion current densities were obtained for the sputtered La coatings ($P_{60}T_{80}t_{60}$) onto AA6061 substrates (17.7 nA cm^{-2}), followed by La coatings under the same deposition parameters onto AA7075 specimens (78.4 nA cm^{-2}). In the case of RE-bilayered coatings, the La/Ce-bilayered films synthesized at $(P_{60}T_{80}t_{60})/(P_{80}T_{80}t_{60})$ onto AA6061 substrates (99.1 nA cm^{-2}) were more prominent than those presented by AA7075 samples under similar conditions

Fig. 8 Scheme of typical Stranski-Krastanov mechanism

(566.6 nA cm⁻²). The cathodic inhibition when La is deposited onto the metallic surface is consistent with previous works obtained by chemical methods. The results confirm that the La deposition prior to Ce films on both metallic substrates allowed to obtain less-imperfect coatings with a small crystallite size (~2.9 nm). Thicknesses of La/Ce films, 284.3 nm for AA6061 and 193.1 nm for AA7075, in comparison with Ce/La (268.6 and 182.1 nm) are also in good agreement with this observation.

In addition, it is also recognized that the charge mobility between the metal surface and the coating-electrolyte interface could also be suppressed with the increase in coating thickness, limiting the kinetics of the cathodic reactions.^[37,64,65] Although coating delamination was not observed during the potentiodynamic measurements, the increase in internal stress-related defects during the sputtering process could also contribute to the deterioration during the corrosion evaluation. The susceptibility of the coated aluminum alloys with RE compounds using the sputtering technique in a chloride-containing solution toward the pitting attack was enhanced in the following order: AA7075/Ce ($P_{60}T_{80}t_{60}$), 1440.6 nA cm⁻² > AA7075/Ce/La ($P_{60}T_{80}t_{60}$)/($P_{60}T_{80}t_{60}$), 949.8 nA cm⁻² > AA7075/La/Ce ($P_{60}T_{80}t_{60}$)/($P_{60}T_{80}t_{60}$), 566.6 nA cm⁻² > AA6061/Ce ($P_{60}T_{80}t_{60}$), 524.5 nA cm⁻² > AA6061/Ce/La ($P_{60}T_{80}t_{60}$)/($P_{60}T_{80}t_{60}$), 195.4 nA cm⁻² > AA6061/La/Ce ($P_{60}T_{80}t_{60}$)/($P_{60}T_{80}t_{60}$), 99.1 nA cm⁻² > AA7075/La ($P_{60}T_{80}t_{60}$), 78.4 nA cm⁻² > AA6061/La ($P_{60}T_{80}t_{60}$), 17.7 nA cm⁻². An approximation of the IE was performed using the relationship $IE(\%) = (1 - i_{corr}/i_{corr}^0) \times 100$, where i_{corr} and i_{corr}^0 are the corrosion current densities of coated and uncoated samples, respectively. Even with the anodic dissolution characteristic of aluminum alloys, La coatings displayed an IE above 95%.

EIS Measurements

EIS is a quantitative tool to assess the corrosion protection afforded by different kinds of coatings; thus, it has been

used to evaluate sputtered RE coatings on commercial aluminum alloys.^[50] For comparison purposes, impedance data obtained for the bare substrates are also shown in the plots.

Figure 12a-f reports the EIS spectra of monolayered and bilayered samples on both aluminum substrates in a 3 wt% NaCl solution. Considering that Nyquist and Bode plots exhibit an expected behavior, an increase in the total resistance with respect to the bare sample can be seen for all the coated samples with different magnitude orders depending on the substrate composition and deposition parameters. There are partially superimposed semicircles corresponding to two or three time constants. The changes in the shapes of the EIS spectra, total resistance, and width of capacitive semicircles are associated with differences in the film roughness and thickness, which conditioned the interaction between the electrolyte and RE coatings, and eventually with the metallic substrate, i.e., the path that allows the solution to interact with the coating through the channels and in time reach the metallic substrate. The highest impedance values were obtained for La coatings on both substrates with R_p values around $2.1 \times 10^6 \Omega \text{ cm}^2$ for AA7075 ($P_{60}T_{80}t_{60}$) and $2.3 \times 10^6 \Omega \text{ cm}^2$ for AA6061 ($P_{60}T_{80}t_{60}$). The phase angle values remained very close to 80°, suggesting the formation and growth of a passive film. The order of the corrosion inhibition for sputtered RE coatings was La > La/Ce > Ce/La > Ce for AA7075, whereas, the order of the provided protection for coated AA6061 substrates was La > La/Ce > Ce/La > Ce. The classical reactions for bare aluminum corrosion involve the metallic dissolution $\text{Al}^{3+} + 3\text{e}^- \rightarrow \text{Al}$, whereas cathodic reactions are $\text{O}_2 + 2\text{H}_2\text{O} + 4\text{e}^- \rightarrow 4\text{OH}^-$ and/or $2\text{H}_3\text{O}^+ + 2\text{e}^- \rightarrow 2\text{H}_2\text{O}$.^[66-68] On the other hand, for coated specimens with Ce films in contact with a NaCl solution can be dissolved as follows:^[69-71]

The cerium oxide compounds are dissolved in an aqueous medium with the subsequent production of OH⁻ ions. Ce⁴⁺ can be reduced to Ce³⁺, increasing the local pH value through the following reaction:

Then, the inhibition mechanism of the corrosion process occurs due to the formation of dense insoluble hydroxide deposits on the metallic surface:

or

Fig. 9 Typical HRSEM images of sputtered bilayered coatings deposited onto AA6061 and AA7075 substrates and their corresponding comparison with pure coatings and bare aluminum, respectively

Eventually, the formation of CeO₂ on the metallic substrate can be possible, providing the so-called self-healing properties of the ceria thin film:

or

On the other hand, La coatings in the aqueous medium can also be dissolved, which propitiate an alkaline environment that leads to the precipitation of lanthanum hydroxides:^[72,73]

The lanthanum hydroxides undergo a hydrated process, resulting in the formation of oxide elements, passivating again the surface:

The interpretation of the measured data for $Z(\omega)$ was carried out by their comparison with the predictions of the theoretical model based on equivalent circuits, and the parameters were established by best fitting of the theoretically calculated impedance plots to experimental ones with a chi-square (χ^2) < 10⁻³. The fitting of experimental

Fig. 10 XRD of RE-bilayered coatings: (a) Ce/La and (b) La/Ce onto Si (100) substrates

data was accomplished using the appropriate electrical equivalent circuits that are shown as an inset in Table 3. The model fitted to the bare substrates with a natural oxide layer has been previously proposed by Jütner,^[74] and it has been used as a reference for the fitting of AA7075 and AA6061 substrates. In the electrical equivalent circuit, R_s represents the solution resistance, R_{ox} is the oxide layer-associated resistance, R_{ct} is the charge transfer resistance, CPE_{ox} is a constant phase element (CPE) related to the electrical oxide film capacitance, and CPE_{dl} represents the CPE of the double layer. In addition to the previous electrical elements, the equivalent circuits for coated samples included R_{film} , coating resistance or pores, and CPE_{film} , used to model the frequency dependence of electrochemical phenomena on the coating. The CPE elements were used instead of an ideal capacitive element due to deviation from an ideal dielectric behavior. The capacitance of CPE can be expressed as follows:^[75]

$$Z_{CPE} = \frac{-1}{(Y_o(j\omega))^n} \quad (13)$$

where $j = \sqrt{-1}$ is the imaginary unit, $\omega = 2\pi f$ is the angular frequency (in rad s⁻¹), f is the frequency in hertz, and n is the dimensionless empirical exponent corresponding to phase deviation. When $n = 1$, the system behaves like a pure capacitor and $CPE = C$. Then, capacitance dispersion is associated with different levels of heterogeneities in the interfacial region. The observation of the fitting parameters shown in Table 3 confirms that the high values of the polarization resistance are obtained with lower surface roughness as a result of the small crystallite size mainly obtained at $P_{60}T_{80}t_{60}$ for La films. The value suggested that RE coatings on aluminum alloys promote a stabilization of the oxide layer, and consequently, high values of R_{ct} are observed. This characteristic is clearly related to a combination of the surface composition and the choice of adequate deposition conditions avoiding re-sputtering during the film growth. The increase in the CPE related to the double layer depending on the RE element deposited on the surface substrates indicates a high level of heterogeneity in the interfacial region, suggesting that more water is penetrating into the RE coating, which in turn reduced the polarization resistance. For both aluminum substrates,

Fig. 11 Polarization curves of RE coatings synthesized at 60 or 80 W ($T = 80^{\circ}\text{C}$ and $t = 60\text{ min}$) and bilayered coatings on (a) AA7075 and (b) AA6061 aluminum alloys

sputtered thinner cerium films were less effective in avoiding the corrosion activity in comparison with lanthanum

coatings, which seem to interact better with the substrate surface during film formation.

Finally, the electrochemical results showed a reduction in the beneficial effect to delay pitting corrosion of aluminum alloys when ceria and lanthanum thin films are intercalated in comparison with La films; however, La/Ce- and Ce/La-bilayered coatings displayed better results in terms of corrosion resistance than those observed for Ce coatings. In general, a compact morphology (smooth) is necessary to reduce the aggressive ion diffusion before reaching the metal substrate.

Based on the morphological observations, it is evident that the power required for the deposition of the second layer provokes erosion of the first layer and a less dense film with pores. However, specific studies are required to determine the main factors that affect the morphology during bilayer formation.

CONCLUSIONS

La, Ce, La/Ce, and Ce/La coatings were deposited on aluminum substrates (AA7075 and AA6061) using RF magnetron sputtering using different deposition parameters. Stoichiometric La₂O₃ coatings with a hexagonal structure are mainly transformed into La(OH)₃ when exposed to the atmosphere. Small peaks of lanthanum carbonates with monoclinic structure were also detected. The reactivity and crystallinity of La films to form La(OH)₃/La₂O₂CO₃ can be fitted by adjusting the sputtering parameters.

Oriented nanocrystalline Ce films can only be obtained at 200°C ($P_{60}T_{200}t_{60}$ and $P_{60}T_{200}t_{25}$). XRD peaks corresponding to the crystalline hexagonal Ce₂O₃ phase were missing, but the XPS measurements confirmed the formation of both Ce⁴⁺ and Ce³⁺ species during the sputtering process, indicating that Ce³⁺ species exist as Ce₂O₃ in an amorphous phase or around oxygen vacancies in CeO₂. The

$\text{Ce}^{4+}/\text{Ce}^{3+}$ in the films varied from 0.97 to 2.84, indicating predominance of Ce^{4+} compounds.

AFM and SEM observations evidenced a typical Stranski–Krastanov-type growth that occurs from a rapid deposition of irregular particles to form islands followed by thickening till entire substrate is covered. This growth

mechanism remained unchanged during the deposition of La/Ce- and Ce/La-bilayered coatings.

The evaluated parameters could be modulated to obtain slightly rough surfaces with more compact morphology; however, the substrate composition in combination with the applied power resulted in determinant factors to inhibit the

kinetics of O₂ reduction/H₂ evolution reactions. AA6061 substrates increased the growth rate of the RE layers and favored the deposition of energetic atoms as stable growth grains in comparison with AA7075 samples.

The deposition of lanthanum coatings on both metallic substrates favored the well-known, self-healing properties in aggressive media. La coatings synthesized at $P_{60}T_{80}t_{60}$ provided an enhancement of up to three orders of magnitude in the barrier properties in comparison with uncoated specimens.

The formation of insoluble and stable lanthanum hydroxides propitiated an increase in the protective properties of the double-layer coating.

The presented results show that the efficiency of RE-sputtered coatings to inhibit the corrosion process of aluminum in chloride media is strongly influenced by the deposition parameters, substrate composition, and in the case of bilayered coatings the way in which they are deposited. The EIS results showed a reduction in the beneficial effect when cerium and lanthanum thin films are intercalated to delaying pitting corrosion of aluminum alloys; unfortunately, RE-bilayered coatings obtained by RF magnetron sputtering did not improve significantly the inhibition of the corrosion process of aluminum in a chloride medium.

Corrosion-Induced Hydrogen Embrittlement in AA2024

G.N. Haidemenopoulos and Helen J. Kamoutsi

Mechanical Engineering, University of Thessaly, Pedion Areos, Volos, Magnisia, 38334, Greece

Abstract

Embrittlement of aluminum alloy 2024 caused by corrosion-induced hydrogen evolution and trapping is discussed in this article. The current literature on corrosion mechanisms, hydrogen trapping, and mechanisms of hydrogen embrittlement is briefly reviewed. Accelerated corrosion tests followed by thermal desorption spectroscopy enabled the identification of hydrogen traps in the microstructure of the material. The nature of these traps was identified by controlled experiments involving solution treatments and plastic deformation prior to corrosion, in order to alter the alloy microstructure. The high-temperature trap is related to the S-CuMgAl₂ phase. In the absence of this phase, hydrogen is trapped in vacancies, which liberate hydrogen at even higher temperatures. The lower temperature trap is related to dislocations. The hydrogen trapped at dislocations increases with plastic strain up to a certain strain and then decreases. The hydrogen generated by corrosion diffuses in the interior of the material and establishes a hydrogen-affected zone beneath the corrosion layer. Removal of the corrosion layer leads to complete restoration of yield strength but only partial restoration of ductility. Removal of the corrosion layer and heating at a high enough temperature to activate all traps for hydrogen desorption leads to complete restoration of ductility. A mechanism of corrosion-induced hydrogen embrittlement is suggested.

Keywords: Aluminum alloy 2024; Corrosion; Hydrogen embrittlement; Hydrogen evolution; Hydrogen trapping; Thermal desorption spectroscopy.

INTRODUCTION

Alloy 2024 belongs to the 2xxx series of Al-Cu-Mg heat-treatable aluminum alloys and has replaced alloy 2017 (Duralumin) as the predominant aircraft alloy. Its widespread applications stem from the excellent combinations of specific strength and fatigue resistance. The corrosion behavior of alloy 2024 has been extensively investigated in the past, with atmospheric, accelerated, and electrochemical testing. In the past two decades, hydrogen evolution during corrosion has been linked to hydrogen trapping in the material microstructure and associated embrittlement. The aim of this article is to review hydrogen evolution during corrosion, hydrogen trapping, and the associated embrittlement of alloy 2024. The article is organized as follows: the microstructure and corrosion mechanisms are discussed in “Microstructure and Corrosion of Alloy 2024” section. Hydrogen evolution and trapping is discussed in “Corrosion-Induced Hydrogen Evolution and Trapping” section, while material embrittlement is presented in “Corrosion-Induced Hydrogen Embrittlement” section.

MICROSTRUCTURE AND CORROSION OF ALLOY 2024

Aluminum alloy 2024 in the form of sheet or plate is extensively used in the aircraft industry for fuselage structures, wing tension members, wing and fuselage skins as well as in shear webs and ribs where stiffness, strength, and high fatigue performance are required. The chemical composition limits are shown in Table 1, whereas the tensile mechanical properties are depicted as a function of temper condition and thickness in Table 2. The remarkable properties of the alloy 2024 are achieved through age hardening. The heat treatment normally involves three stages: (a) solution treatment at a temperature within the single-phase α region, in order to dissolve all the alloying elements; (b) quenching to room (or lower) temperature, in order to obtain a supersaturated solid solution (SSSS); and (c) natural or artificial aging for the decomposition of the SSSS, in order to form finely dispersed precipitates for precipitation hardening. The precipitation sequences of both binary Al-Cu and ternary Al-Cu-Mg alloys are the following.^[1–13]

Table 1 Chemical composition (wt%) of aluminum alloy 2024

Element	Cu	Fe	Si	Zn	Ti	Mn	Mg	Cr	Others Total
	3.8–4.9	0.50	0.50	0.25	0.15	1.2–1.8	1.2–1.8	0.10	0.15

^aStrength decreases as thickness increases.

SSSS $\rightarrow$ GP $\rightarrow$ $\theta'' \rightarrow \theta' \rightarrow \theta$ (CuAl_2) for Al–Cu alloys

SSSS $\rightarrow$ GPB $\rightarrow$ $S' \rightarrow S$ (CuMgAl_2) for Al–Cu–Mg alloys

Both of the above precipitation sequences involve the formation of fully coherent Guinier–Preston (GP) copper zones or Guinier–Preston–Bagariatsky (GPB) copper-magnesium zones. These zones evolve during aging to semicoherent intermediate phases (θ'' , θ' , or S') and to the final equilibrium incoherent precipitates θ (CuAl_2) or S (CuMgAl_2) for the binary Al–Cu and ternary Al–Cu–Mg alloys, respectively. In some cases, the alloys are cold worked (e.g., by stretching 5%) after quenching and before aging, thus increasing dislocation density and providing more sites for heterogeneous nucleation of intermediate precipitates. Transmission electron microscopy (TEM) microstructures of 2024-T351 are presented in Fig. 1. The peak-aged condition is depicted in Fig. 1a and b indicating the precipitation of semicoherent S' on dislocations. The overaged condition is depicted in Fig. 1c indicating the precipitation of rod-shaped equilibrium S (CuMgAl_2).

Microstructure and corrosion of AA2024 have been reviewed recently.^[14] Regarding corrosion resistance, it is well known that aluminum forms a strongly bonded protective oxide film when exposed to the atmosphere, which when damaged reforms immediately in most environments. This film passivates aluminum in the pH range of about 4–8.5. Beyond these limits, aluminum corrodes in aqueous solutions because its oxides are soluble in many acids and bases, yielding Al^{3+} ions in the former and AlO_2^- (aluminate) ions in the latter.^[15] Aluminum alloy 2024 is susceptible to atmospheric corrosion in industrial or coastal areas. Therefore, these alloys should be protected when exposed to these conditions. Alloy 2024 can be protected by a thin coating of pure aluminum or corrosion-resistant aluminum alloy; the resulting

product is called Al-clad alloy 2024. This cladding is metallurgically bonded to one or both sides of the sheet or plate and may be 1.5%–10% of its overall thickness. Any corrosion that might occur propagates only to the cladding–core interface and then spreads laterally, thus making cladding very effective in providing cathodic protection to the core alloy.

Alloy 2024 is less corrosion resistant than other aluminum alloys with lower amounts of copper. Copper's inhomogeneous distribution in the matrix results in pitting and stress corrosion cracking (SCC).^[16–18]

From studies in different corrosive environments, it was concluded that Cl^- ion is the most aggressive ion leading to pitting corrosion.^[19] Due to the intense presence of Cl^- ions, the marine environment is highly corrosive.^[20] The mechanism involves adsorption of Cl^- , formation of intermediate complexes and soluble species, thinning of the oxide film, and finally direct attack on the core metal.^[21] Contributing to the initiation of corrosion is also the second-phase particle present in 2024, mainly the S phase (CuMgAl_2) and the $(\text{Cu, Mn, Fe})\text{Al}_6$ and/or Cu_2FeAl_2 particles.^[22,23] Pits usually first appear on grain boundaries, by selective dissolution of particles, if the boundary precipitates are anodic with respect to the matrix and the precipitate free zone. In the opposite case, the neighboring area poor in compound elements is attacked.^[24] Pitting on grain boundaries due to selective generation of anodic regions has been reported in the work of Sugimoto et al.,^[25] Urushino and Sugimoto,^[26] and Garner and Tromans.^[27] The anodic nature of grain boundaries has also been attributed to the segregation in these regions, with regard to the grain interior where galvanic cells are activated.^[28]

Intergranular corrosion is another form of corrosion of alloy 2024, which has been the subject of numerous investigations, especially for the classical composition of Al–4%Cu alloys.^[29] Intergranular corrosion has been attributed to the difference in the breakdown potentials of

Fig. 1 Transmission electron micrographs of aluminum alloy 2024-T351. (a) Peak-aged condition. (b) High magnification of (a), and the precipitation of semicoherent S'-phase on dislocations is evident. (c) Overaged condition, characterized by precipitation of rod-shaped equilibrium S (CuMgAl₂)

Al₂Cu particles along the grain boundaries of aged alloy Al-4%Cu and the surrounding Cu-depleted zones, which contain only 0.2%Cu.^[30] After the dissolution of the grain boundary precipitates, the boundaries are susceptible to corrosion because they are more anodic in comparison with the rest of the matrix.^[31] TEM investigations of Al-4 wt% Cu foils demonstrated that the alloy was more susceptible to intergranular corrosion in the underaged condition.^[27] The intergranular corrosion is possibly linked to pitting

corrosion. As depicted in Fig. 2a, pitting formation and pit coalescence at the grain boundary lead to intergranular corrosion depicted in the atomic force microscopic image of Fig. 2b in a alloy 2024-T351 exposed for 12h in an exfoliation corrosion (EXCO) solution specified by ASTM G34-90.

Alloy 2024 is also susceptible to exfoliation corrosion, which is highly influenced by the environmental conditions. It has been shown that forged truck wheels made of 2024-T4 exfoliate severely in only 1 or 2 years in areas, where deicing salts are used on the highways during the winter months.^[32] Mainly responsible for the development of this type of corrosion are the compositional variations present due to grain boundary precipitation discussed previously. The elongated grains and the directionality of the microstructure have a detrimental effect on the development of intergranular cracks typical of exfoliation corrosion.^[33–36] It has been shown that in a 2B06 alloy (similar to 2024), exfoliation corrosion initiated from hydrogen-assisted intergranular cracks when the material was exposed to tropical marine atmosphere.^[37] A typical appearance of exfoliation corrosion of alloy 2024-T351 is presented in Fig. 3. The sample was exposed for 96h in the EXCO solution specified in ASTM G34-90.^[38] The directional attack along the elongated grain boundaries, common for exfoliation corrosion, is observed, followed by the removal of the outer material layers.

In the presence of high stresses, alloy 2024 is subjected to SCC.^[39] Environments that cause SCC are usually aqueous, and the presence of a specific chemical species, usually chloride ions, is essential.^[40,41] Over the years, a large number of possible mechanisms for SCC have been proposed. The most commonly accepted mechanism for SCC in Al–Cu–Mg alloys is anodic dissolution-assisted cracking.^[25,29,30,42,43] SCC has been linked to hydrogen uptake. For example, it has been reported that for 7xxx alloys, the initiation of SCC necessitates a critical concentration of hydrogen buildup at potential crack sites.^[44] More recently, it has been documented that hydrogen plays a major role in the degradation of the mechanical properties and is linked to embrittlement of alloy 2024.^[45] Studies of embrittlement of pure Al in humid air indicated a major role of hydrogen.^[46] In particular, the intergranular crack path and the reversibility of the phenomenon (recovery of ductility after degassing) supported a hydrogen rather than an anodic dissolution mechanism. In a recent study,^[47] where glycerine was used as a noncorrosive environment, it was shown that Al–Zn–Mg–Cu–Zr alloy underwent hydrogen embrittlement even in laboratory air (having a relative humidity of ~50%). Similar trends were found in the work of Scamans and Tuck^[48] after measurements of hydrogen permeability and stress corrosion resistance of an Al–Mg–Zn alloy, as functions of quench rate and aging treatment. Several research results have been reviewed in the work of Speidel^[49] for Al–Mg–Zn alloys. The kinetics of crack growth of aluminum alloy 7050 in a humid air environment was considered in the work of Young and

Scully,^[50] confirming that hydrogen embrittlement was the controlling mechanism. Evidence for hydrogen uptake and its effect on the crack growth for the low-strength alloy 5083 is summarized in the work of Jones.^[51] Hydrogen evolution during corrosion, trapping, and embrittlement of alloy 2024 are discussed in the next sections.

CORROSION-INDUCED HYDROGEN EVOLUTION AND TRAPPING

During corrosion, hydrogen evolution can take place in an aqueous acidic solution by the cathodic reaction:

In a H_2O -rich environment and with the possible presence of Cl^- anions, hydrogen is produced by corrosion reactions at the surface of the material, and part of it is absorbed into

the material.^[52] In particular, the process of atomic hydrogen production by a single-electron transfer, according to the reaction

makes water an aggressive environment for aluminum alloys.^[50] Absorbed hydrogen diffuses toward the interior of the material and may be trapped at various preferential locations. It has been shown^[53,54] that lattice defects (vacancies, dislocations, grain boundaries) and precipitates supply a variety of trapping sites. Hydrogen traps are mechanistically classified as reversible and irreversible,^[55] depending on the steepness of the energy barrier needed to be overcome by hydrogen to escape from them. These traps can be thermally activated and liberate hydrogen at different temperatures.

In order to investigate hydrogen uptake and trapping, a variety of methods to introduce hydrogen in the microstructure have been used over the years, such as exposure to aqueous environments and humid air,^[56] cathodic charging,^[57] and exposure to a corrosive environment.

Thermal desorption spectroscopy (TDS) along with permeation techniques are the most well-established methods for determining hydrogen uptake. Permeation gives information about the diffusivity of hydrogen through the bulk of the material but does not distinguish between the active trapping sites present in the alloy microstructure. This information can be obtained by thermal desorption methods combined with gas chromatography or mass spectroscopy. A schematic representation of an in-house TDS system is shown in Fig. 4. The setup consists of a furnace with a system of automatic temperature control, a supply of inert gas (high-purity nitrogen), and a gas chromatograph.

This approach has been successfully adapted to the studies of hydrogen trapping in various materials with

Fig. 4 Thermal desorption setup, utilizing a gas chromatograph and a thermostated furnace. Carrier gas is N₂. Reprinted by permission from the work of Kamoutsi et al.,^[45] Elsevier

body-centered cubic (BCC) and face-centered cubic (FCC) structures^[45,58–60] as in nickel,^[58,61] pure aluminum,^[60,62,63] Al–Cu, Al–Mg₂Si,^[53] Al–Li alloys,^[63,64] Al–Li–Cu–Zr,^[65] as well as pure iron and steel.^[66–68] It has also been combined with accelerated corrosion tests in order to characterize corrosion and hydrogen absorption in alloy 2024.^[35,36] In the last two works, the existence of multiple trapping states was confirmed, and the quantity and evolution pattern of hydrogen was discussed.

TDS measurements have been combined with heat treatments for second-phase precipitation or dissolution, as well as cold working for dislocation multiplication in order to determine the constitution of trapping sites in nickel, steel, pure aluminum as well as Al alloys.^[53,60,69–71] Hydrogen uptake and trap binding energy were determined for Monel K-500 in several conditions (solid solution, aged and cold worked microstructures), using TDS.^[72] The results suggested hydrogen trapping at incoherent γ' (Ni₃Al) precipitates. Transport and trapping of hydrogen in nickel has been investigated in the work of Lee, S.-M. and Lee, J.-Y.^[70] It was shown that dislocations in nickel act as trapping places of hydrogen, and the activation energy of these traps seems to be lower than that for the bulk diffusion of hydrogen. It was proposed that in nickel, hydrogen diffuses along short-circuit routes through the grain boundaries, but hydrogen is also trapped at grain boundaries. The effect of grain size on hydrogen diffusion and trapping mechanisms has been investigated for a wide range of grain sizes in non-textured pure nickel in the work of Oudriss.^[58] The conclusion was reached that hydrogen diffusion is intensified along the boundaries but may decrease when the dislocation density stored in the boundary becomes considerable.^[58,61]

Regarding hydrogen trapping in aluminum and aluminum alloys, TDS has been performed in pure aluminum in the work of Young and Scully.^[60] The desorption spectra revealed three distinct trapping states. The lowest energy peak was attributed to hydrogen occupying interstitial lattice sites. The intermediate peak around 400°C was associated with hydrogen trapped at dislocations, whereas the 500°C

trap state was associated with vacancies. Relevant work in the work of Izumi and Itoh,^[62] investigated hydrogen trapping states in pure aluminum foils of 99.99% purity with different amounts of blisters by means of TDS. Blisters as well as vacancies have been recognized as potential sites of hydrogen trapping. More specifically in aluminum alloys, it has been shown in the work of Saitoh et al.^[53] and Itoh et al.^[54] that lattice defects (vacancies, dislocations, grain boundaries, subgrain boundaries, interfaces), second-phase particles, and precipitates supply a variety of trapping sites. Tritium microautoradiography was employed to study hydrogen trapping in high-purity aluminum, Al–4Cu, Al–Mg₂Si, and Al–6Zn–2Mg (wt%) alloys in the work of Saitoh et al.^[53] and Iijima et al.^[73] These works indicated that, in general, microstructural features possessing a tensile stress field act as hydrogen traps, while those having a compressive stress field act as hydrogen repellers. In some alloys, trapping was observed at dislocations produced by cold work and at interfacial dislocations associated with tensile elastic stress fields. The effect of hydrogen on the hardness of 7075-T6 aluminum alloy has been investigated in the work of El-Amoush.^[74] The surface of 7075-T6 aluminum alloy was hardened by the introduction of hydrogen. Further charging increased the depth of the hardened region. Transmission electron microscopy observations of the hardened hydrogen-enriched layer revealed an increase in dislocation density. Aging after hydrogen charging had as a result either the complete or partial recovery of hardness depending on the charging conditions applied to the material. Hydrogen enrichment was also determined in a 2050 Al-alloy subjected to cyclic corrosion tests in aqueous NaCl solutions.^[75]

Corrosion-induced hydrogen uptake and subsequent trapping have been extensively investigated in the work of Charitidou et al.,^[35] Haidemenopoulos et al.,^[36] Kamoutsi et al.,^[45] and Kamoutsi et al.^[76] Results from these works will be summarized here. Alloy 2024-T351 has been subjected to accelerated corrosion by immersion in EXCO solution specified in ASTM G34-90.^[38] Hydrogen is introduced by the cathodic hydrogen reaction. Hydrogen uptake and trapping were studied by TDS, using the system previously mentioned in Fig. 4. A TDS spectrum is depicted in Fig. 5, where the peaks correspond to respective trapping states. Four traps named T1, T2, T3, and T4 are depicted. The last three traps are irreversible since no hydrogen evolves below the respective critical temperature. The first trap T1 is a reversible trap since it releases hydrogen continuously at temperatures close to ambient temperatures. Calculation of the total hydrogen quantity liberated from each trapping site is performed by integrating the area under the respective peak. The results are shown in Fig. 6 as a function of exposure time in the corrosion solution. The three irreversible traps exhibit saturation, indicating depletion of the available trapping sites. Trap T4 is the first to saturate and exhibits the highest desorption temperature. It is therefore considered as the strongest trap.

Fig. 5 Desorption spectrum of H_2 in specimens of aluminum alloy 2024-T351 for continuous heating up to 600°C. Thickness of material is 1.8 mm. Reprinted by permission from the work of Kamoutsi et al.,^[45] Elsevier

The hydrogen spectra presented in Fig. 5 provide some clues about trapping states, based on the temperatures where hydrogen evolution takes place. During the thermal cycle of hydrogen desorption, the material undergoes microstructural

changes. A comparison between the hardness of corroded and uncorroded materials that experience the same heating history is shown in Fig. 7, and the differences are set in perspective with the hydrogen spectra. As expected, the hardness of the uncorroded material declines with temperature up to 400°C due to overaging (a slight increase at 250°C is connected with a secondary aging peak), whereas it rises again above 400°C due to dissolution and re-precipitation. A similar behavior is exhibited by the corroded material. However, there are two distinct differences in the hardness values. The corroded material is softer than the uncorroded up to 300°C and harder above 350°C. The first temperature region includes T1 and T2 states. Hydrogen in the T1 state is trapped in interstitial sites, whereas T2 hydrogen is trapped at particle/matrix interfaces. Recently, it was suggested that hydrogen might assist dislocation motion by altering the binding energy between dislocations and solute atoms.^[77,78] On the other hand, hydrogen at matrix/particle interfaces might alter the interaction energy between dislocations and particles for coherency hardening in a way similar to that proposed for lattice dislocation. The result is that hydrogen in T1 and T2 states most likely aids dislocation motion in overcoming either the lattice resistance or the semicoherent particle resistance, and the corroded material appears softer.

Fig. 6 Amount of hydrogen desorbed from the four trapping states (T1–T4) as a function of exposure time in the corrosive solution. Reprinted by permission from the work of Kamoutsi et al.,^[45] Elsevier

Fig. 7 Microhardness profile versus temperature and hydrogen spectrum for alloy 2024-T351. Reprinted by permission from the work of Kamoutsi et al.,^[45] Elsevier. HV, hardness Vickers

The second temperature region (above 300°C) incorporates states T3 and T4. It is presently argued that T3 hydrogen is trapped at dislocations, whereas T4 hydrogen is trapped in the main hardening phase S-CuMgAl₂. As is apparent from Fig. 7, hydrogen affects the dissolution and re-precipitation processes or even the overaging (coarsening) process in the alloy and the corroded alloy appears harder. However, more work is needed to clarify this behavior.

In an attempt to gain a better insight into hydrogen trapping in aluminum alloy 2024, experiments were designed to alter the material's microstructure prior to corrosion exposure and associated hydrogen uptake. In the first set of experiments, the material was solution treated and quenched (condition SQ) prior to corrosion exposure. This condition is compared with the standard solution-treated, quenched, and aged (SQA) condition in order to reveal the effect of the S-CuMgAl₂ phase on hydrogen trapping. Details regarding the experimental procedures are described in the work of Kamoutsi et al.^[76]

The desorption spectrum for both the SQ and SQA series is shown in Fig. 8. It should be noted that the spectrum is divided into two parts. The first part corresponds to the ramped spectrum where the temperature is increasing at a constant rate (10°C/min), whereas the second part corresponds to isothermal holding since after the furnace reaches 600°C, the specimen is kept at a constant temperature of 600°C until all hydrogen is degassed. Due to the short corrosion exposure times (6 and 12 h), the hydrogen produced by the corrosion process is not enough to reveal all trapping states identified in the work of Kamoutsi et al.^[45] and, therefore, only the strong trap state T4 appears. Comparison of the SQ and SQA curves shows a marked decrease in the amount of hydrogen trapped in the T4 state for the SQ

series for both exposure times of 6 and 12 h. This result suggests that the T4 state is mainly associated with the S-phase (Al₂CuMg), since this phase is absent in the SQ specimen. Hydrogen trapping at the S-matrix interface as has also been suggested in the work of Saitoh et al.^[53] In addition, it has been indicated, by atom probe tomography, that the S-phase acts as a hydrogen trap in AA2024 alloy.^[79]

The desorption spectra of Fig. 8 exhibit some additional interesting points. Regarding the SQA series, the onset of hydrogen desorption occurs at a lower temperature, while larger quantities of hydrogen are degassed for the material exposed for 12 h relative to the one exposed for 6 h. This is

Fig. 8 Spectrum of hydrogen evolved from the solution treated and quenched specimens (SQ), as well as solution treated quenched and aged (SQA), after 6 and 12 h in the EXCO solution. Reprinted by permission from the work of Kamoutsi et al.,^[76] Elsevier

attributed to the higher quantity of hydrogen uptake and, therefore, more effective filling of the T4 trap for SQA-12 h.

The onset of hydrogen desorption for the SQ series is displaced to higher temperatures relative to the SQA series. This suggests that, in the absence of the S-phase, hydrogen is being trapped in a stronger trap site in the SQ specimens. This trap should be associated with vacancies that were thermally formed during the solution treatment of the SQ specimens. These vacancies were frozen in after the quench and acted as hydrogen trap sites during the corrosion exposure. The slightly lower hydrogen trapped in the SQ specimen after 12 h exposure time compared to the specimen exposed for 6 h could be attributed to the higher extend of annealing out of the thermal vacancies. After 12 h exposure, more hydrogen is introduced, but the vacancies to trap the hydrogen are fewer. Hydrogen trapping in vacancies has also been documented in pure aluminum, where the vacancies constitute the strongest trap state with desorption temperature at about 500°C.^[57,60]

In the second set of experiments, the material was plastically deformed at certain levels of plastic strain prior to corrosion exposure, in order to reveal the effect of dislocations on hydrogen trapping. Again, details regarding the experimental procedures are described in the work of Kamoutsi et al.^[76]

The ramped desorption spectra of the deformed specimens are shown in Fig. 9. The undeformed specimen is also included for comparison. The results indicate that prior deformation affects mainly hydrogen trapped at state T4, which is associated with the S-phase and in a smaller degree state T3. The effect can be better analyzed if the total quantity of hydrogen (area under the peak) is plotted as a function elongation in Fig. 10. Regarding state T4, which is associated with the S-phase, there is no significant change in the quantity of trapped hydrogen up to a

Fig. 9 Spectrum of hydrogen evolved after different levels of deformation. Reprinted by permission from the work of Kamoutsi et al.,^[76] Elsevier

Fig. 10 Total quantity of hydrogen evolved after different levels of deformation for the four trapping states. Reprinted by permission from the work of Kamoutsi et al.,^[76] Elsevier

strain of 6%. At higher strains, however, there is a marked and monotonic decrease in the hydrogen trapped at state T4 with increasing plastic strain. At higher strains, interactions between dislocations lead to the formation of a dense dislocation network as well as the formation of dislocation loops around the particles of the S-phase. Hydrogen diffusion toward the S–matrix interface is hindered, because it is either trapped at the tensile stress centers of the network or repelled by the compressive stress centers of the network. The trapped hydrogen at the network is considerably less than the hydrogen that could be trapped at the S–matrix interface, in the absence of the surrounding dislocation loop network. Thus, it is suggested that plastic deformation could generate a “dislocation shielding” effect that reduces the hydrogen trapped by the S-phase.

Regarding state T3 (Fig. 3), it exhibits an increase in trapped hydrogen up to 6% elongation, while the amount of hydrogen trapped decreases at higher elongation. According to Scully,^[60] in pure aluminum, the trap appearing around 400°C is associated with dislocations. The increase of trapped hydrogen up to 6% elongation could be attributed to the increased dislocation density with plastic strain. However, at higher plastic strains, corresponding to stage III hardening, the high stacking fault energy of aluminum alloys hinders dislocation dissociation and favors cross slip. Thus, the dislocation density may be reduced due to cross slip and annihilation of screws of opposite sign. The overall effect is a reduction in hydrogen trapped at higher plastic strains.

CORROSION-INDUCED HYDROGEN EMBRITTLEMENT

Prior to the discussion of hydrogen embrittlement of the alloy 2024 due to corrosion, a short review of hydrogen embrittlement mechanisms is necessary. Although over

the past 50 years, extensive research has been focused on hydrogen embrittlement of aluminum alloys, there is still much debate on the prevailing mechanisms involved. Hydrogen-enhanced localized plasticity (also known as HELP), hydride formation, and hydrogen-enhanced decohesion (HEDE) are among the mechanisms proposed. The bulk of research results deals with 7xxx alloys, while the work on 2xxx alloys is rather limited. Recent reviews on the mechanisms of hydrogen embrittlement have been performed by Lynch^[80] as well as by Robertson et al.^[81]

The HELP mechanism was introduced in the early 1970s to explain the hydrogen embrittlement in steels. It is based on the observations that hydrogen diffusing in front of a crack tip and through the material lattice actually enhances dislocation movement rather than hindering it.^[82] The theory was adopted for BCC and FCC crystal structures.^[83–85] With in situ TEM observation of the fracture process in real time, with vacuum or H₂ atmospheres, it was observed that hydrogen increased the dislocation mobility under constant stress, while the reverse effect was true with the removal of hydrogen and restoration of vacuum. Similar observations and conclusions were reached for pure aluminum.^[86] Ab initio studies, using the Peierls–Nabarro model of dislocation stress fields, were performed in Al, to study the interaction of interstitial hydrogen with dislocations. Hydrogen was found to form a strong bond at dislocation cores, depending on the type of dislocation, and it lowered the Peierls stress of dislocations by more than an order of magnitude.^[87]

Another highly attributed hydrogen embrittlement mechanism in aluminum alloys is HEDE. This mechanism works under the same initial assumptions as the HELP mechanism described previously. Through interaction between the corrosive media and the material surface, atomic hydrogen forms and is subsequently absorbed in the material. Then it diffuses in the areas in front of crack tips, which are characterized by high triaxiality. According to the HEDE mechanism, hydrogen in these regions leads to a loss in the cohesive strength, thus enabling crack advance.^[80]

Hydride formation of either Al^[88] or microstructural phases other than aluminum (e.g., Mg- or Li-containing phases) has been detected in a few studies.^[89,90] The implicit assumption is that hydrides are brittle phases with limited fracture toughness and very low fracture strength, being only a small fraction of the theoretical fracture strength of Al. Thus, the formation of hydrides of continuous secondary phases at key locations, such as along grain boundaries, provides an alternative mechanism for embrittlement in aluminum alloys. However, detection of hydride formation is difficult due to the intervention of effects such as electron beam decomposition of hydrides, loss of hydrogen during specimen preparation, and stress-sensitive solvus behavior where hydrides dissolve upon unloading.

The adsorption-induced dislocation emission mechanism is described in the work of Lynch.^[80] According to this mechanism, hydrogen adsorption facilitates dislocation

emission from crack tips by the weakening of interatomic bonds. This dislocation activity results in crack advance or crack opening and promotes material embrittlement.

Regarding the corrosion-induced hydrogen embrittlement of alloy 2024, the first issue to be resolved is how deep into the material does the hydrogen produced during the corrosion process penetrate. Sequential sectioning of pre-corroded samples (exposed to the EXCO solution for 24 h) indicated that hydrogen penetrates the material beyond the maximum depth of corrosion attack the work of Kamoutsi et al.^[45] These results, reviewed here, indicate the presence of a hydrogen zone beneath the corrosion zone. The 24 h exposure was selected because, at this time, the hydrogen trapped in the strongest trap state T4 reaches saturation, as indicated in Fig. 6. Representative photos from the corroded surface after 24 h exposure are shown in Fig. 11, depicting pitting formation as well as pit interaction and clustering (Fig. 11a). The maximum depth of attack, as determined from rigorous metallographic

Fig. 11 Alloy 2024-T351, after 24 h exposure in the corrosive solution EXCO: (a) SEM topography exhibiting pit-to-pit interactions and pit clustering on the surface; (b) metallographic section exhibiting the depth of attack

sectioning in, the work of Kamoutsi et al.^[45] was 350 μm ; a representative micrograph is shown in Fig. 11b.

Tensile specimens were exposed for 24 h in the EXCO solution, and the following conditions were considered: corroded specimens (C), corroded specimens from which the corrosion layer of 350 μm was subsequently mechanically removed (CR), corroded specimens heat treated at 495°C for 35 min followed by air cooling for hydrogen desorption (CH), and corroded specimens with both corrosion removal and heat treatment (CRH). Similar specimens were prepared as reference from uncorroded material (U), uncorroded material subjected to removal of 350 μm by machining (UR), uncorroded material subjected to the same heat treatment at 495°C/35 min (UH), and finally uncorroded material subjected to both material removal and heat treatment (URH). Any additional hydrogen that might have been generated during machining is negligible, and in any case, it is the same in CR and UR specimens.

Tensile test results are provided in Fig. 12. The data for conditions C, CR, CH, and CRH are presented as percentages of the respective reference values (U, UR, UH, and URH). The corroded material (condition C) exhibits a yield strength of 92% with respect to the reference uncorroded material (condition U); however, the elongation is quite low at only 39% the reference value. Heating of the material for hydrogen desorption (condition CH) did not affect the yield strength, relative to UH; however, it restored ductility to 56% of the reference value (condition UH). Removal of the corrosion layer (condition CR) restored the yield strength to 100% with respect to reference (condition

UR), while ductility was partially restored to 66% of the reference (UR). Removal of the corrosion layer, followed by heating to 495°C/35 min (condition CRH), fully restored both the yield strength and elongation almost to the reference value (condition URH).

Analysis of the results indicated that corrosion affects a surface layer of the material by introducing defects such as pitting, exfoliation, and intergranular cracks. These defects act as initiation sites for cracks; thus, they degrade the strength of the material. Removal of material up to the maximum depth of corrosion attack removes all the above defects and subsequently restores strength. Ductility is also degraded by corrosion but is not fully recovered by removal of the corroded layer. This constitutes evidence of a bulk mechanism of embrittlement. Subsequent heating of the material, to a temperature high enough where all hydrogen traps are activated to release hydrogen, fully restores ductility, implicating hydrogen embrittlement as the responsible mechanism.

Further evidence of a hydrogen mechanism comes from the results of fractographic analysis of tensile specimens (condition C) presented in Fig. 13. The most interesting finding is that a quasi-cleavage (embrittled) zone always appears between intergranular corrosion and the ductile uncorroded matrix. This observation is consistent with the existence of a hydrogen-affected zone, which degrades the ductility of the material even when the corrosion layer has been removed.

The proposed mechanism of hydrogen-induced embrittlement of alloy 2024 is sketched in Fig. 14. Corrosion creates damage, which penetrates in a nonuniform way from

Fig. 12 Results of tensile tests as percentages of the respective reference values. C/U: corroded relative to the uncorroded material. CH/UH: corroded and heat treated relative to uncorroded and heat treated. CR/UR: corroded and removal of corrosion layer of 350 μm relative to uncorroded and removal of a layer 350 μm . the surface to the interior of the material, establishing a corrosion layer. Below the corrosion layer, a hydrogen zone is established due to the diffusion of hydrogen generated by the corrosion reactions (Fig. 14a). The elongation at this stage is at 39% that of the reference condition (U). Removal of a uniform layer equal to the depth of attack (corrosion layer) removes all the corrosion damage and all hydrogen trapped in the corrosion layer. The result

is an elongation increase to 66% of the reference value. However, part of the hydrogen zone still remains in the hydrogen-affected zone beneath the corrosion layer (Fig. 14b). Heating of the alloy to 495°C liberates all hydrogen (Fig. 14c) and restores ductility back to the original value. A similar hydrogen zone beneath the corrosion zone has been observed in alloy 2024-T351 subjected to cyclic corrosion tests.^[91] A mechanism involving hydrogen contribution to the degradation of the alloy mechanical properties after cyclic exposure of AA2024 to chloride media has also been proposed.^[92] According to this mechanism the volume expansion of the electrolyte trapped in intergranular defects leads to stress fields, which promote hydrogen diffusion and trapping.

CONCLUSIONS

This article reviewed the issues of corrosion-induced hydrogen evolution, hydrogen trapping, and associated corrosion-induced hydrogen embrittlement in aluminum alloy 2024. From the work presented, the following conclusions can be made:

- Hydrogen is produced during the corrosion process and is being trapped at distinct microstructural traps in the interior of the material.

Fig. 14 Proposed mechanism for corrosion-induced hydrogen embrittlement in AA2024. Reprinted by permission from the work of Kamoutsi et al.,^[45] Elsevier

- The temperature of hydrogen evolution during TDS and the microhardness variation with heating provide indirect evidence for the nature of the traps.
- Solution treatment prior to corrosion indicated that the high-temperature (500°C) trap T4 is associated with the S-CuMgAl₂ phase. In the absence of the S-CuMgAl₂ phase, hydrogen is being trapped in vacancies. The vacancies liberate hydrogen at slightly higher temperature than the S-CuMgAl₂ phase.
- Plastic deformation prior to corrosion exposure revealed that the trap T3 (400°C) is associated with dislocations. Hydrogen trapped at dislocations increases with plastic strain up to a certain strain, above which hydrogen trapped at both T3 and T4 decreases.
- The hydrogen generated by corrosion diffuses in the interior of the material and establishes a hydrogen-affected zone beneath the corrosion layer.
- Removal of the corrosion layer leads to complete restoration of yield strength but only partial restoration of ductility.
- Removal of the corrosion layer and heating at a high enough temperature to activate all traps for hydrogen desorption leads to complete restoration of ductility.
- The above results constitute an evidence of corrosion-induced hydrogen embrittlement in aluminum alloy 2024.

Creation of Master Alloys for Aluminum

Michael M. Gasik

Helsinki University of Technology, Espoo, Finland

Vladislav I. Mazur

National Metallurgical Academy of Ukraine, Dnipropetrovsk, Ukraine

Abstract

This article addresses the use of master alloys used primarily for grain refinement of aluminum and its alloys. However the use of master alloys for microstructure and property control is also discussed. Specific topics include: principles and classification of master alloys, physical metallurgy of basic master alloy systems, applications of master alloys, and techniques for microstructure modification and property improvement.

Keywords: Casting; Crystallization; Grain refinement; Master alloys; Phase transformation.

INTRODUCTION

This chapter deals with master alloys and other technologies, primarily directed at the grain refinement of aluminum and its alloys. Less discussed, but also very important, are issues of the microstructure formation and resulting properties of cast aluminum alloys as a result of applications of master alloys, modifiers, and special processing methods. Close control of the cast structure is a major requirement in the production of high-quality aluminum alloys. The most recently used method to provide a fine and uniform as-cast grain structure is to add nucleating agents to the melt to control crystal formation during solidification.^[1–4]

There exist many books, articles, and technical papers on master alloy manufacture, properties, and applications, to which the reader is encouraged to refer for more details (some, but not all, of them are listed in the references). In this book, we would like to present a more general outline of the basic issues (what these master alloys are, why they are needed, how to apply them) from the engineering point of view. The goal was also to point out the advances in aluminum alloy processing, which are often not taken into account by alloy manufacturers and users.

“Master Alloys for Aluminum” section of this chapter briefly describes the need for master alloys and their basic types and forms. “Physical Metallurgy of Basic Master Alloy Systems” section and part of “Master Alloy Application” section consider the physical metallurgy of master alloys and their application practice. The rest of “Master Alloy Application” section, as well as “Advanced Techniques for Microstructure Modifications and Property Improvement for Aluminum Alloys” section, describes novel techniques for grain refinement, microstructure, and property control in general. It is assumed that the reader is familiar with the general practice

of aluminum alloy manufacture as well as phase equilibrium diagrams (these subjects are covered in other chapters of this book and are thus not included here explicitly).

MASTER ALLOYS FOR ALUMINUM

Principles of Master Alloys

One of the most important goals of aluminum alloy production by casting is the refinement of grain size, because coarse grain size immediately reflects in lower property levels. In the case of fixed smelting and casting conditions, this goal is usually achieved by different modification methods. These methods are conventionally based on the introduction of a small amount of special master alloys into a slightly overheated melt. During crystallization, the nature and appearance of the master alloy(s) play the main role in the grain size refinement.^[5]

- element solubility in the aluminum solid solution, binary, or multi-component compound(s) according to the stable and metastable phase stability diagrams
- surface properties (surface tension, adhesion between phases, adsorption, etc.)
- intermetallide morphology
- their particle size distribution
- their distribution uniformity
- processing parameters (heating/cooling rates, temperature, time)

The first issue remains the main one for the development and selection of master alloys for particular grain refinement or modifying effects. It is based on the stable phase diagrams,

assessed theoretically and experimentally, as well as on the chemical thermodynamics of the alloy systems.^[6-9] The basic idea of “master alloys” has its grounds in the fact that many alloying elements are very active (Sr, Ti, Mg) or are just unsuitable (Na, B) to be entered in a pure form into aluminum alloys. Also, the production of purified metals like strontium or sodium with the purpose of dissolving only a small amount of addition (0.01–0.2%) is obviously not a cost-effective method. Many active metals can be manufactured much more easily in their alloy form (Al–Ti, Al–Sr, Al–Mg) due to lower activity of the leading elements. The dissolution of the master alloy in the melt also proceeds under a different mechanism than that of pure metals.

The master alloys used most often for aluminum contain titanium and other transition metals. These master alloys have been extensively studied for many years and are available commercially from different manufacturers.^[1-5,10] It is necessary to note that the chemical composition of the master alloys is only one, but not the most important, parameter to characterize their efficiency as grain refiners.

Often, master alloys are compared on the basis of the intermetallide particles that already exist in the master alloy^[5] and act as seeding nuclei during crystallization of the melt, influencing, in this way, the grain growth. For example, for Al–Ti–B master alloys, the best modification effect was obtained with spheroid particles of TiAl_3 of 300 μm and $\text{TiB}_2 < 3 \mu\text{m}$.^[2,5]

In the case of Al–Si alloys, so-called primary silicon crystals as well as silicon-rich phases remain in the liquid even at high temperatures (800–1200°C). In this case, the morphology and the size distribution of silicon crystals will determine the final grain size of the alloy, and thus, modifiers should affect first the silicon rather than aluminum crystals. Many master alloys (like Al–Sr) are used mainly for the purpose of modifying, and not primarily grain refinement. On the other hand, some additions, like sodium, do not eventually affect the crystallization process by forming some intermetallides – rather, they change surface tension, adsorption, and other similar properties locally, and in this way prevent or assist the crystallization of one or another phase type, its polytype, or compound.^[8]

There are also master alloys with combined effect, acting as both grain refiners and modifiers. For example, an Al–10% Sr–2% B alloy (StroBor®) is used for this purpose.^[4] Unlike traditional grain refiners, this master alloy has no titanium – rather, it takes advantage of the fact that both primary and secondary Al–Si foundry alloys already contain some titanium, either as a deliberate addition or as residual titanium in the scrap. Major intermetallic phases present in this master alloy include SrAl_4 and SrB_6 . Upon addition to the foundry melt, these phases go into solution, and boron reacts with titanium present in the melt to form intrinsic TiB_2 , which then serves as nuclei for grain refinement during solidification. This mechanism is different from that of the Al–Ti–B master alloy, which already has TiB_2 particles before alloying.

Laboratory tests were carried out on alloy 356 (7.0% Si–0.21% Fe–0.33% Mg–0.10% Ti) for specimens solidified at a rate of 0.8°C/s.^[4] In this example, both master alloys were added to the melt at equivalent boron levels of 0.004% B, which, in the case of the StroBor alloy, also results in a 0.020% Sr addition. Both master alloys were added to an electric resistance furnace and held for a period of 3 hr. The furnace was not stirred during the holding period in order to assess the degree of fade in grain refiner performance with time. As shown by the grain sizes observed, both master alloys are effective grain refiners and produced essentially the same grain size. Following a 0.2% addition by weight of StroBor, the eutectic phase in the abovementioned test was fully modified and exhibited a finely “differentiated” fibrous structure.

Such master alloys^[4,11] may have different compositions (7.5% Sr–1.3% B, 10% Sr–1% B, 10% Sr–2% B) and may also contain additional titanium (7.5% Sr–1.7% Ti–1.4% B). The selection of the master alloy is thus dependent upon the main problem to be solved (grain refinement, modification, properties adjustment, etc.).

Classification of Master Alloys

There exist a variety of master alloys for aluminum and aluminum alloys, depending on the principal (leading) element. Most master alloys have a special color code (Table 1) and classification numbers provided by the Aluminum Association (AA) and the European Standardization Committee (CEN). This assists in easier identification of the master alloys. Some of the master alloys with uncommon content of the leading element(s) have no AA or CEN coding, but may have color coding, or vice versa. For example, Al–10% Sr–1% Ti–0.02% B master alloy (AA code H2017) has one light blue and one red stripe, and it is not listed in Table 1. Some plants produce their own kinds of master alloys in different tailored forms, often with a very high content of alloying elements (75–99%), and assign a special color code to them. This coding is sometimes not officially registered, but helps factory users to distinguish these alloys from other master alloy types. It is necessary to point out that the color coding of master alloys in the United States and in Europe may be different (Table 1), so every manufacturer has to ensure that master alloys are properly coded to avoid possible confusion.

Master alloys are available in a variety of forms: waffle ingot, notched ingot, slab ingot, sheared ingot, button, splatter (flake), broken ingot, coiled rod, Korrext™ bar, and cut rod, depending on the leading element, manufacturing procedure, and the purpose of the master alloy itself (Table 2).

Besides “standard,” or better said, the most common, master alloys (Table 1), there are many experimentally developed master alloy types for a variety of applications. The majority of them seem to have no international standards or clear domestic regulations (e.g. factory developments for their own needs). For example, several master

^anS = number of stripes.

Note: Color coding of master alloys in the United States and in Europe may be different, and some sources have reported different colors used for the same elements, for instance: chromium – light blue (CEN), orange, purple (AA); iron – green (CEN), black (AA); manganese – silver gray (CEN), brown (AA); zinc – white (CEN), not specified (AA). Table 1 may serve as a guideline only, and thus, users are advised to consult the original standards and the color system used to avoid possible confusion.

Table 2 Typical commercially available product forms of master alloys

Master alloy product form (Common name)	Typical nominal specifications	
	Metric	English/American
Pigs, Piglets	0.45–0.50 kg	~1 lb
Waffles (in plates)	6.5–7.7 kg	14–17 lb
One kilogram notched ingots	~1 kg	~2.2 lb
Slab ingots	~18 kg	~40 lb
Pyramid-shaped buttons	0.23 kg	8 oz
Buttons	0.14–0.23 kg	5–8 oz
Sheared ingots ^a (cut cast bars)	0.34–3.63 kg	0.75–8 lb
Broken ingots (irregular pieces)	6.5–100 mm	0.25–4 in.
Flakes	0.03–0.3 kg	1–10 oz
Korrek bars ^b	~11.2 g/linear cm	~1.0 oz/linear in.
Rods (cut)	0.15, 0.33, 0.50, or 1.0 m	5.75, 12, 18, or 36 in.
Rods (in coils)	For 9.5 mm diameter: 180, 272, 454, 1360 kg	For 3/8 in. diameter: 400, 600, 1000, 3000 lb

^aThe cut bar is taken from a continuous cast trapezoidal bar with a cross-sectional area of 1.78 in. Each inch weighs ~2.75 oz (0.078 kg). Products that are available in this form are, e.g., Al-Ti-B, Al-Ti-C, Al-Ti, and Al-Sr master alloys.^[4]

^bKorrek bar is the trademark name of KB Alloys, Inc., for a 0.9 in. (23 mm) extruded bar. Products available in this shape are, e.g., Al-5% Be and Al-10% Sr.

Table 3 Rare Earth (RE) master alloys, atypical types

Composition ^a	Typical applications	Main effects
Al–(5–22%) Si–(Me)–RE1	Al–Si cast alloys for pistons and similar applications	Grain refinement, minimizing gases and voids, improving wear resistance and strength, decreasing thermal expansion
Al–(4–8%) Cu–RE1	Al–Cu heat-resistant cast alloys	Decreasing cracking, enhancing strength and heat resistance (350–400°C)
Al–RE2	Soldering Al alloys	Improving solderability

^aMe = Cu, Mg, Mn, Fe; RE1 = La, Ce, Y; RE2 = Ce, Mischmetal.

alloys with rare earth (RE) metals have been developed and tested in China (Table 3) for Al–Si and Al–Cu cast alloy grain refinement etc.^[12] Most compositions have about 10% RE (near the eutectic composition of the Al–RE systems) to keep lower liquidus temperature (640–700°C). Higher-order master alloys (Al–Mg–Si–Fe–RE etc.) are also being used for deformed aluminum alloys (wire, cable, home products, foil, engineering and construction of Al–Mg and Al–Zn alloys). Due to many application fields, the comparison of RE influence on the alloys' properties has to be done on a case-by-case basis.^[12]

The microstructure of the master alloy plays an important role in the final modification effect. For instance, for “conventional” Al–Ti–B alloys, the average grain size of intermetallic compounds may vary significantly in different master alloy specimens (Table 4). Eventually, the grain refinement effect from master alloys of similar compositions will be different for alloys with 500 µm and 5 µm of TiAl₃ grain size.^[5] For the examples of Table 4, the noticeable grain refinement effect at the level of 0.02–0.03% Ti was achieved by adding Al–2% Ti rod, and the best one – by Al–Ti–B master alloy (soaking time 4–5 min at 730–740°C). Rods and Al–Ti–B piglets have kept their modifying activity up to 60 min of soaking, but Al–1.8% Ti piglets – up to 80 min.^[5] Similar results have been obtained for Al–Ti–B master alloys in both rod and piglet form^[3] – the best grain size of 170–200 µm at the 0.0075% Ti level was received after 20 min (rod) and 160 min (piglets) soaking time. The effect above was mainly caused by smaller grain size of the rod master alloys than that of piglets. Smaller crystalline alloys have high solubility kinetics in aluminum, so their modifying effect may be reached almost immediately after introduction in the

melt.^[3,5] However, this does not automatically guarantee that rod-type master alloys are always better than piglets.

A comparison was made for short soaking times (up to 5 min) and lower titanium contents (<0.08%) for different master alloy types (Table 4). Here, the Al–Ti–B master alloy was superior to all the Al–Ti alloys studied.^[5] The Al–Ti rod has had the least modifying effect, far less than that of the Al–Ti–B piglets, despite the same grain size of the TiAl₃ intermetallics. One of the possible reasons for this is the weaker stability of deformed intermetallics in comparison with refractory TiB₂ particles present in the Al–Ti–B piglets.

This example suggests that master alloy product data sheets should also have such parameters included as intermetallic mean grain size, microstructure, and the manufacturing method. This will assist in the most proper selection of the master alloys for specific aluminum alloy processing.

PHYSICAL METALLURGY OF BASIC MASTER ALLOY SYSTEMS

Phase Equilibria

Details of the Al–M (M=master alloy leading element(s)) phase equilibria may be found in numerous handbooks on phase diagrams^[6–9] and in databases as well as dedicated publications, including this book. Usually, these stable phase diagrams are used for master alloy design, because they are directly related to both master alloy processing and master alloy application.

In master alloy processing, the main issues are the liquidus surface of the system in question and the

Table 4 Example of the composition and structure of the Al–Ti–B master alloys (all master alloys are obtained from different manufacturers)

Alloy number	Composition (%)	Form of the master alloy	Microstructure parameters (TiAl ₃ Phase)	
			Morphology	Average length (µm)
1	1.8 Ti	Piglet	Needles	300–800
2	4.5 Ti	Waffle plate	Needles	100–200
3	4 Ti	Centrifugal cast	Needles	40–60
4	5 Ti	Granule	Disperse needles	5–8
5	2 Ti	Rod	Disperse needles	6–10
6	4.5 Ti, 1 B	Piglet	Blocks	10–15

thermodynamics of the Al–M solutions. The “ideal” system should have:

- optimal liquidus temperature (e.g. 50–100°C lower than that of the basic aluminum alloy)
- low vapor pressure (in the case of magnesium and some non-metals)
- reasonable activity of the alloying element (low activity helps to prepare the master alloy, higher activity helps in the reaction of the master alloy with the molten aluminum bath)
- suitable intermetallic compounds formed during either production or application of the master alloy

The following common additions are used for aluminum alloys, and the engineering practice has acquired the following main addition methods for them:^[13]

- Boron is added to precipitate transition metal impurities such as Ti and V, and so improve electrical properties. It is mainly added as a dilute master alloy (<1% B).
- Bismuth is added both as the pure metal and as a dilute master alloy to enhance machinability of the aluminum alloys.
- Chromium prevents grain growth in Al–Mg alloys, inhibits recrystallization in Al–Mg–Si and Al–Mg–Zn alloys, and corrects for Fe to produce a golden color in anodizing. The main addition form is the concentrated tablet or briquette, although a significant quantity is also added as dilute master alloy.
- Copper is added mainly to increase strength, and it is added in many forms (pure metal, master alloys, concentrated tablets, and powder injection).
- Iron improves the high-temperature strength of some kinds of alloys. Addition forms are similar to that for copper.
- Magnesium provides high strength with good ductility, together with excellent corrosion resistance and weldability. For Al–Si alloys, it also improves heat treatment ability. It is mostly added as the pure metal, although master alloys are also widely used.
- Manganese improves strength and also plays a role in preventing recrystallization. The main technique of addition is as concentrated tablets or briquettes, powder injection, and, to a lesser extent, master alloys.
- Lead, like bismuth, is principally used to enhance machinability. The main method of addition is as the pure metal, although concentrated tablets and master alloys are also used.
- Silicon is used in “foundry alloys” (silumines) as it gives excellent fluidity in casting. It is also used in extrusion alloys, to which it contributes high mechanical properties. The main method of addition is as pure metal, but significant amounts are added as master alloys and through powder injection.
- Strontium is added to modify the eutectic in Al–Si alloys. It is mostly added as a dilute master alloy.
- Titanium provides an important contribution to grain refinement. It is mainly added as tablets (including pure metal), but most often through master alloys.
- Zinc is used to improve strength. It is almost exclusively added as the pure metal.
- Zirconium is added to inhibit recrystallization. It is mainly added as a master alloy (up to 15% Zr), but also as a concentrated tablet.

One may see that the variety of alloying elements and respective phase equilibrium diagrams do make it very difficult to define “optimal” liquidus temperature or “reasonable” activity. The situation is more complicated when the master alloy has several alloying elements. For example, Fig. 1 shows the phase stability diagram for the Al–Ti–B system at 700°C expressed through partial pressures of boron and titanium in the gas phase (equilibrium state). It is seen that very small variations of boron or titanium “pressures” may result in changes of the intermetallic compounds and thus phase composition of this master alloy.

The most important use of thermodynamics of the Al–M system has, for many years, been in master alloy production. Irrespective of the method used (mixing of technically pure metals, reduction from salts, co-reduction from ores and mixed raw materials, etc.), the process should use the optimal driving force (minimal Gibbs energy of the system) to ensure proper recovery of useful elements with cost-effective technology. Gasik and Emlin^[14,15] have described major methods of such master alloy processing (see Chapter 2 of this volume).

Whereas chemical thermodynamics assists in selection of the manufacturing process, care should be taken on the kinetics side to get purer master alloys with proper microstructure. In some cases, refractory intermetallides, which

Fig. 1 Calculated phase stability diagram for the Al–Ti–B system at 700°C (pure components, ideal solutions) in the coordinates of partial pressures of titanium and boron

contain “harmful” elements (for certain types of aluminum alloys, they may be Fe, Ni, Mn, or Cr), could be filtered out of the melt. This is not possible for master alloys that already have “useful” intermetallides (TiB_2 , Al_3Ti , etc.), so a small amount of impurities may trigger undesirable crystallization of the master alloy and affect its properties.

In general, phase equilibria and chemical thermodynamics (element activities in the melt, partial and integral properties (enthalpy, entropy)) are very important issues in answering the question: could this particular composition of the master alloy be produced within practically reasonable conditions (temperatures, gas pressures, used refractory linings, etc.)? If yes, then engineering implementation of the master alloy production could consider specific aspects of the process (charge materials, furnace type, metal and slag handling). If not, then the process may be still possible by, for example, reducing targeted element concentration (this will reduce its activity and thus improve thermodynamic prerequisites for the alloy formation).^[14,15]

A special role of thermodynamics and metal physics is in understanding the mechanism of modification by certain master alloys. Analysis of electronic structure and pair interactions in the Al–Si–Fe–Mn–Mg–O system has led to the formulation of the hypothesis^[36] that the most effective master alloy modifiers (X) for Al–Si castings will be those that decrease the orientations of the Si–X and O–X bonds.^[16,17] The main result of the modifier is branching of the eutectic and Si-rich phases with their isotropic growth. This is explained by partial dissolution of X atoms in the lattice of the Si-rich phase, assisted by, e.g., hydrogen impurities (blocking Si–H, O–H bonds) and opposed by oxygen (formation of highly directed Si–O–Si bonds).^[16,17] If modifiers are added in excess, aluminum could form Al–X intermetallides, thus masking the effect of modification but in some cases suppressing excessive grain growth. Within this approach, there are no “good” or “bad” modifying elements, because their combined effect in the presence of other elements or impurities may be opposite to that of the addition of only one modifying element.^[36]

It is worth noting that there are other hypotheses explaining the modifying effects for aluminum and its alloys, and so far, there is no solid evidence to fully support one or another hypothesis.

Metastable Phases

According to modern understanding of the melt structure,^[5,18] the melt is not a homogeneous liquid but a colloidal solution with small particles and clusters, enriched by one or a few components of the alloys. This state can exist for a few milliseconds or hundreds of hours in a wide temperature range, may transform into another such state, and may be destroyed only after substantial overheating beyond the liquidus line.^[5] If these small particles have sizes larger than the critical radius of the nucleus, they may act as seeds for melt crystallization (Table 5). On the other hand,

Table 5 The general crystallization route for alloys. T_h —homogenization temperature, T_{cryst} —crystallization temperature

Temperature	Melt composition	State of the alloy
$T \gg T_h$	Near-ordered or disordered liquid	Overheated melt
$T \geq T_h$	Atoms and clusters in dynamic equilibrium	Melt
$T_h > T > T_{\text{cryst}}$	Clusters and colloidal particles	Melt
	Prenuclei and crystallization centers	Melt
$T_{\text{cryst}} \geq T$	Overcooled liquid (Often metastable)	Solid, semi-solid or melt
$T_{\text{cryst}} \gg T$	Solidified alloy (Crystals)	Solid

if clusters have stoichiometry and near-order parameters too far from the phase coming up during crystallization, they cannot satisfy the orientation-dimensional principle (Dankov’s principle) and thus cannot act as crystallization seeds. Instead, they may stay in the liquid until very low temperatures and trigger the formation of phases not normally seen in the “phase equilibrium.” Obviously, the mechanism of the grain refinement in this case will be different even if the aluminum alloy and the master alloy compositions remain the same.

Skiprov^[18] has determined the critical radius of nuclei as

$$r_{\text{crit}} = \frac{2\sigma T_0 v}{(L\Delta T)} \quad (1)$$

where σ – melt/crystal interface surface tension, T_0 – equilibrium temperature of crystallization, v – crystal specific volume, L – latent heat of transformation, ΔT – liquid phase undercooling vs. equilibrium temperature. It was experimentally confirmed for a variety of aluminum alloys that not only ΔT values, but also T_0 values depend on the initial charge grain size and processing history (metalurgical heritage effects). For Al–12% Si alloy cooled at 3.1K/s from the same temperature, only alloys with initially coarse grains retained the equilibrium eutectic temperature (577.1°C) with $\Delta T \sim 6.1\text{K}$. If the alloy had small grain size before melting, T_0 decreased by 7.5 K with $\Delta T \sim 4\text{K}$. Alloys with different processing history but crystallized in the same conditions have shown a clear dependence on the crystallization kinetics and temperature values.^[5] According to formula (1), the critical radius of the colloidal silicon particles in these alloys should be $\sim 50\text{ nm}$, which is very close to that of the silicon particles separated from the Al–Si melts by centrifugal sedimentation technique and experimentally observed in rapidly solidified thin films^[8] (Fig. 2).

Fig. 2 Primary crystal sizes (μm) found in rapidly solidified aluminum alloys quenched from different temperatures – Al–Si thin quenched solid film ($\blacklozenge$), quenched drop ($\blacksquare$), Al–Si modified by sodium (Δ), Al–Cu ($\times$)

One of the most possible ways of grain size refinement by modifiers is also lowering of the liquid/crystal surface tension. With Eq. (1), it will significantly lower the critical work A_{crit} necessary for the formation of nuclei, since $A_{\text{crit}} \sim 32\sigma^3 \{T_0/(L\Delta T)\}^2$.^[5] In the case of modifying of cast Al–Si alloys by sodium, the surface tension is estimated to decrease from 0.85 ± 0.003 to $0.617\text{--}0.797\text{ N/m}$ (i.e. by 7–30%), which may decrease the critical work for nucleation almost twice. It is necessary to say, however, that this surface tension is extremely difficult to measure as a function of temperature, crystal, and alloy prehistory as well as treatment time, so only occasional data have been published on that.

On the basis of Table 5, it is clear that the mechanism of the modification and, respectively, the grain refinement effect will depend not only on the modifier type and form, but also on the “point of the state” of the alloy (function of alloy’s temperature). It was observed that no single reasonable hypothesis exists to describe a variety of metal solidification phenomena.^[16]

A. V. Mazur^[19] has carried out a review of the analysis of structure-sensitive properties of Al–Me systems (Me=Zn, Cu, Mg, Si). For example, melt viscosity is considered to be one of the most sensitive properties to reflect structural changes in the melts. In pure Al, the viscosity curve has two “jumps” – at 770°C and 850°C . In the Al–Si system, the first one shifts to $790\text{--}805^\circ\text{C}$ and the second one to $845\text{--}865^\circ\text{C}$ (depending on the silicon concentration). The first temperature shift increases for higher silicon percentage.^[19] A similar picture exists in the Al–Cu ($770\text{--}800^\circ\text{C}$ and $855\text{--}870^\circ\text{C}$) and Al–Mg ($790\text{--}800^\circ\text{C}$ and $880\text{--}890^\circ\text{C}$) systems. For the Al–Mg system, however, the second curve jump disappears in alloys with $>20\%$ Mg, and the second one for $>40\%$ Mg. The Al–Zn system seems to have no viscosity anomalies, at least in the ranges and temperatures studied. Thus, different alloy systems have different structures of liquid phase and hence crystallization mechanism and kinetics. At the modern level of metallurgical science, the effect of metastable

phase formation as well as possible heritage effects should always be considered when processing structure-sensitive alloys and cast components.

MASTER ALLOY APPLICATION

Common Practices for Master Alloy Use

Common master alloys with a range of different Ti/B or Ti/C ratios (Table 1) are available to accommodate special conditions that may exist in the user’s plant.^[4,11] In selecting the proper grain refiner alloy, the user must take into consideration conditions such as the alloy to be treated, the quantity of recycle or secondary aluminum used, the desired grain size in the product, and the melting and casting practice used.^[4] The method of introduction of master alloys into the melt depends on the purpose, the alloying element, and the manufacturing process. For instance, master alloys may be added in the furnace before melt release or in the mold just before the solidification starts. They may also be added in mixers, intermediate ladles, channel induction furnaces, transfer launders, semi-automatic bulk charging systems, and precise compositional adjustment for smaller foundries. Lumpy and cut forms of master alloys (Table 2) require weighing and subsequent feeding into the melt. Continuous rods may be submitted automatically from the coils, e.g., into a metal jet poured out of the furnace, into the mold, etc. There are a variety of feeding systems for the master alloys, and every factory uses the one best suited for their particular conditions.

Besides traditional forms of master alloys, i.e. ingots in particular forms, other shapes for their application have been developed. One of these forms is the master alloy briquette. It contains a controlled mixture of alloying element (75–85% or more) in powder form, aluminum powder, and/or a sodium-free non-hygroscopic flux. The briquettes are produced by compressing the powder components between pillow-shaped indentations on two opposing rollers. Dissolution of the briquettes relies on the alloying element powder particles forming aluminides. It is recommended that the briquettes be charged after melting is completed and the bath has been skimmed at $>720^\circ\text{C}$. Normal furnace stirring to ensure a uniform mixture is sufficient to assure complete dissolution of the briquettes. The flux aids in removal of the oxide film found on a powder particle to expose the metallic element to molten aluminum, promoting rapid dissolution.

A similar principle is used in alloying tablets, such as ALTABTM, for the precise compositional adjustment of alloy melts. These tablets are usually a mixture of alloying element (75–99%) in powder, sponge, or needle form, aluminum powder, and/or a flux. In the case of tablets or briquettes, the goal is more uniform distribution of alloying elements within the melt bath, faster dissolution of the master alloys, and more precise control of the metal properties.

The application of master alloys to Al–Si casting requires more careful consideration than for pure aluminum. Here, both grain refinement, and silicon dendrite and eutectic growth happen at the same time, so several acting mechanisms could result in uneven grain size distribution in the cast products. Authors^[20] have studied the effect of Al–Ti–B master alloy additions on dendrite arm spacing (DAS) in the Al–8% Si–2% Cu alloy (DIN 226 S) rather than simply on grain size. It was independently shown^[5] that elongation of all modified Al–9% Si alloys is inversely proportional to the square of DAS:

$$\delta, (\%) = \frac{11.42 + 7.024 \times 10^{-4}}{d^2} \quad (2)$$

where DAS (d) is expressed in millimeters. With different additions of titanium by Al–2% Ti master alloy, the effect of the Ti/B ratio from 1/6 to 6 has been investigated^[20] for casting from 750°C. Without boron additions, titanium at the 0.13% level eventually decreases the grain size (from 1.1 to 0.5mm), but no further improvement is achieved at higher titanium content. Moreover, the DAS refinement is most efficient (from 35 to 20 μm) at 0.11% Ti, increasing with higher titanium content. Authors have conducted a regression analysis of these trends (Figs. 3 and 4), which indicate that the minimal grain size of 0.365 mm may be achieved at 0.17% Ti and a Ti/B ratio of about 0.22. On the contrary, the minimal DAS is achieved at 0.11–0.13% Ti and Ti/B ~ 2. Thus, the manufacturer will have to consider which property will be the most important to get after casting. It is necessary to note that there is no single opinion about the mechanism of the Al–Ti–B master alloy impact on the grain size and the DAS. Hu and Li^[20] have explained it by complicated interactions of Ti, Al, Si, and B, but they did not study the effect of temperature and soaking time, which are very important kinetic parameters, or the possibility of metastable phase formation.

Fig. 3 Estimation of the average grain size in Al–8% Si–2% Cu vs. Ti percentage and B/Ti ratio. Points are experimental data^[20]

Fig. 4 Estimation of the average dendrite arm spacing (DAS) in Al–8% Si–2% Cu vs. Ti percentage and B/Ti ratio. Points are experimental data^[20]

In another work,^[21] the influence of Ti, Na, and Sr additions (independently and simultaneously) to the Al–7% Si–Mg alloys was studied. The grain refinement and mechanical properties were measured for alloys poured from 720°C. Titanium was introduced as Al–3% Ti–1% B master alloy, Na as metallic sodium in aluminum cans, and strontium as Al–9.9% Sr master alloy.^[21] The titanium content was reported to be 0.18–0.19% (“with recommended range of 0.1–0.2%”), but results of the previous study (Figs. 3 and 4) show that there is a large difference between 0.1% and 0.2% Ti.^[5,20] No boron content has been mentioned (from the master alloy composition it may be estimated as ~0.05%, B/Ti ~ 0.33 – quite far from “the optimal”). Although authors have found an effect of Ti, Na, and Sr on grain refinement, they have reported no significant increase in mechanical properties as a function of Ti, Ti–Na, or Na–Sr additions. This work illustrates typical underestimation of other casting parameters as well as the history of the alloy and initial state of the master alloys. Without such information, it is often not only impossible, but also misleading to draw any conclusions about the effect of certain kinds of master alloys or modifiers.^[5,19]

As a main guideline, one has to remember that no “optimal” Ti/B ratio or Ti percentage exists for any alloy without exact reference to the processing parameters. As shown below, holding the melt at different temperatures may result in achievements quite the opposite of the expected ones.

Alternative Techniques For Master Alloy Addition

Conventional master alloys for grain refining in aluminum are inserted into the melt in their solid form (rods, waffles, lumps, etc.). For the Al–5% Ti–1% B master alloy, fine TiB₂ and TiAl₃ particles in the alloy are thus already present in the system, and the effect of grain refinement would

obviously depend on the master alloy's "intrinsic" quality (morphology, particle size distribution, surface properties of these phases, etc.). Additional operations like thermal-mechanical treatment of the alloy to make preshaped rods or wires may also impact the efficiency of the refinement.

Solid master alloys need some time for dissolution in the molten aluminum. The kinetics of the dissolution will affect the refinement result together with the master alloy quality. To get the maximal effect, an incubation time of a few minutes is usually required for the uniform distribution of the alloying element through the melt. It was shown^[22] that addition of the liquid master alloy would reduce this time period at least three times (from 15 to 5 min) and improve the refinement effect. It is necessary to note that preparation of the liquid master alloy and its dosing may present some additional difficulties in the manufacturing practices.

In some cases, there are limitations of manufacturing of the master alloy itself. For instance, Al-5% Ti-1% B alloy is often prepared by the introduction of KBF_4 and K_2TiF_6 salts into molten aluminum, followed by crystallization of the melt and rolling.^[1,23] Since the idea of grain refinement by means of this master alloy application is based on the formation of fine TiB_2 particles, it was suggested^[23] that such particles be produced separately, in the form of a nanopowder (2–30 nm, specific surface area 20–30 m²/g) by plasma chemical synthesis. Such powders of TiN and TiCN were shown to significantly improve the properties of aluminum and decrease the grain size. Due to difficulties in the handling and processing of nanopowders in smelter and foundry factories, it was also suggested that special pellets of these powders be formed in a thin aluminum shell (master alloy pellets of Al-2.7% Ti). Introduction of such pellets of 8% wt. at 670–680°C with the following heating and crystallization^[23] resulted in ~30% finer structure of 99.5% Al in comparison with modification of the sponge master alloy Al-2% Ti. The disadvantage of this process is that complete dissolution of the pellets requires rather high overheating temperatures of the aluminum bath (1380–1400°C). As shown in the last part of this chapter, the effect of overheating and subsequent soaking may easily mask or overcome the effect of the master alloy addition, so such results should be considered with care.

It also worth noting that alternative techniques for adding master alloys are being extensively studied all over the world, but most of them are being applied for specific conditions only, and these results are unfortunately more or less ad hoc. As in the case of master alloy characterization, maximum information about experimental conditions is desired to be included with the results of the master alloy applications.

Novel Techniques for Grain Refinement and Property Monitoring

Traditional casting and foundry technology still remains a very complicated system, with many unclear links between

the major processing parameters. It does not fully ensure correct information transfer from the starting charge to the final ingot stage.^[5] The main question discussed above was the grain refinement process, but one may certainly ask: why do we need essentially smaller grain sizes – would it not be wiser to speak about the higher properties? In the casting of aluminum alloys, this is a very important question.

Earlier, the main goal of casting was to obtain smaller grain size, because the connection of the smaller grain size to better properties like strength and toughness is very well known in metallurgy. The practice, however, taught that a small grain size does not automatically guarantee high and stable property level. This has turned engineers and scientists to look in greater detail into the mechanism of the crystallization process and the morphology of the resultant phases.

As shown earlier, the composition and the structure of the melt (aluminum, alloys, or any other metals) is not always a homogeneous or near-ordered liquid (Table 5). Despite this fact being known for years, the utilization of the melt properties (i.e. before adding any modifiers) first for grain refinement is not extensively used in industry. The influence of heating temperature and casting temperature on the grain size of aluminum are demonstrated in Ref. [24]. When pure aluminum melt is poured from 820°C, a rapid increase of the grain size is observed. This temperature was not influenced by the addition (<0.6%) of any metal (Be, Mo, W, Ti, Fe, Cu, Mn, Zr), but when impurities added were over 1%, this temperature decreased to 810–815°C. There is also numerous experimental evidence of anomalous electrical conductivity, oxidation kinetics, viscosity, density, and other properties.^[5,18,19,25] It was suggested that molten aluminum has the following transformations in the liquid state:^[19]

- FCC-1 → BCC at 800–900° C.
- BCC → FCC-2 at 1150–1250°C.
- FCC-2 → CP at 1390–1450° C.

It is worth noting that earlier works did not find such anomalies or deviations of diffusion coefficient or electrical conductivity.^[26,27] However, these anomalies have an order of magnitude of ~5%, which is much lower than the experimental error of 10–15% reported by earlier works. New experimental methods like electron and neutron beam as well as high-resolution X-ray diffraction have reasonable sensitivity, and their data leave no doubts about the complicated structure of molten aluminum and other metals, and other phase or phaselike transformations in the liquid state.^[8,19,28] This information has recently been used for the development of new grain refinement and property improvement technologies. The novel techniques for grain refinement may be generally listed as:

- use of metallurgical heritage effect (variations in composition of the melting charge)

- use of thermal–temporal treatment (modification of temperature program and soaking times)
- use of external energy sources (laser, plasma, electron beam furnaces) to destroy clusters and associates and thus to impact the final microstructure of the alloy

In this section, mostly the first (use of metallurgical heritage) and the second (temperature and time) methods will be considered. They become more and more important due to the increased amounts of recycled aluminum alloys. The charge compositions, microstructure, and alloying elements all influence the quality of the aluminum ingots. The knowledge of this influence is essential for the production of high-quality alloys.

The effect of metallurgical heritage (processing history) of the master alloys has been studied for Al–Ti and Al–Ti–B master alloys.^[5] Master alloys with 1.5–5% Ti and 0–1% B have been produced by conventional casting into a pig iron mold (25–30 mm), centrifugal casting into a pig iron mold (5–6 mm), roll-casting between water-cooled rolls (1.5–2 mm), extrusion from ingot into the rod (10 mm), self-propagating high-temperature synthesis (SHS), and single and double remelting of the cast master alloy with mold casting.

The aluminum batch of 100 g was melted and heated up to 750°C. Master alloys were introduced into the melt for 0.01%, 0.005%, and 0.1% Ti respectively, stirred over 20 min and cooled in an alumina crucible at a low cooling rate (<30 K/min). It was found that for master alloys of the same composition, their manufacturing method has a strong influence on the modifying effect. For instance, SHS-made Al–2% Ti master alloy resulted in the same grain refining effect at 0.05% Ti as for Al–5% Ti–1% B master alloy at the 0.12% Ti level or cast Al–5% Ti master alloy at the 0.1% Ti level.

Similar results have been obtained for modification of the Al–6.5% Mg alloy. It was discovered that the Al–5% Ti–1% B master alloy produces practically the same results as boron-free Al–4% Ti–0.3% Mg or Al–1% Ti–0.2% Mg master alloys at the level of 0.02–0.04% Ti.^[5] After heat treatment, the highest strength values of 300–305 MPa were obtained for Ti/Zr=1.5 and Ti+Zr=0.23% (Fig. 5) for the pressure-cast master alloys. In the case of Al–Ti and Al–Zr master alloys made of “fresh” charge, the maximal effect of 300 MPa was achieved at the level of Ti+Zr=0.33% (higher titanium and zirconium contents substantially increase hydrogen concentration). Thus, the use of pressure-cast master alloys allows one to get similar or higher results with 30–40% less addition of master alloys in comparison with the conventional type.^[5]

In many cases, the scrap of the same alloy is used during processing (remelting, recycling). After a certain period of time, returnable scrap and metal wastes have significantly higher concentration of alloying (modifying) elements and undesirable additions, which requires a respective adjustment of the modifying technique. For the case just shown of

Fig. 5 Strength of the Al–6.5% Mg alloy after addition of Al–Ti and Al–Zr master alloys vs. modifier concentration and Ti/Zr ratio. Points are experimental data^[20]

Al–6.5% Mg alloy, the use of charge with 50% own scrap and an addition of 3–10% of the same but pressure-cast alloy has required less master alloy addition. The same mechanical properties of 300 MPa strength and slightly higher elongation (25% in comparison with 20% for conventional) have been obtained with Ti+Zr = 0.17% and Ti/Zr = 1.2.^[5] Similar results were reported for Al–Cu alloys as well. This confirms the importance of knowledge of the maximal number of parameters of the alloy manufacturing process to select the proper modifying route.

For the Al–9% Si alloy, special experiments have been conducted,^[5] and correlation relationships were revealed for recommendation of the charge composition versus alloy casting parameters for the average ingot wall thickness of

- 10–20 mm → ~3% of pressure-cast alloy, ~0.5% flux modifier, and 700 ± 10°C.
- 20–40 mm → ~5% of pressure-cast alloy, ~0.65% flux, and 690 ± 10°C.
- 40–60 mm → ~7.5% of pressure-cast alloy, ~0.75% flux, and 680 ± 10°C.

Here, the amount of pressure-cast alloy (scrap) of the same composition (i.e. Al–9% Si) should be introduced in the molten alloy, preferably in molds. These recommendations generally hold for the same “fresh” charge. If the amount of recycled own scrap is significant, the situation changes (Fig. 6). Here, one may see that flux modification (1–1.5%) is only advantageous for fresh charges. When the scrap percentage is over 40–50%, the addition of flux modifiers makes things only worse, and the best way is to keep flux under 0.5%.^[5] Generally, the use of scrap with small grain size is almost as effective as the use of traditional modifiers and thus decreases master alloy expenditure by two to four times.

Maximal values of the properties (strength, elongation, etc.) are sometimes not the main goal in castings. In many cases, the stability of the properties from batch to batch and from one ingot to another is more important. For Al–7% Mg

Fig. 6 Tensile strength of Al–9% Si alloy vs. recycled scrap percentage and the addition of flux modifiers. Points are experimental data^[20]

alloys, these optimal processing parameters have been found as 675–685°C pouring temperature, 0.05–0.08% Ti, and 0.7–1.0 Ti/Zr, depending on the wall thickness.^[5]

Many works^[5,19,25,29–32] have demonstrated the influence of the thermal–temporal treatment (TTT) on the properties of aluminum and other alloys. For example, the eutectic Al–12.4% Si alloy has been prepared from pure elements at 750°C, heat-treated at different temperatures (Table 6) and then quenched from the liquid state.^[32] Regimes 1 and 2 have corresponded to the preservation of the microstructural inhomogeneity in the melt, whereas overheating to >1000°C should destroy associates and clusters in the melt. The results, such as DAS and the eutectic’s microhardness, clearly indicate that suitable overheating temperature and soaking time may produce ingots with similar or even better properties than those with added master alloys or modifiers.^[32] This TTT technique is discussed in greater detail in “Advanced Techniques for Microstructure Modifications and Property Improvement for Aluminum Alloys” section

Generally, two main guidelines may be formulated for grain refinement:^[5]

- addition of specially made or collected alloys (including casting or rolling scrap) with small crystalline size to the charge – this will introduce seed nuclei of smaller size and thus have a modifying effect on the grain size

- melt overheating to high temperatures and/or reasonable holding time at the isothermal conditions – this leads to structural changes in the liquid state (decomposition or phase changes in clusters, associates, disperse particles) and initiates the crystallization process according to the meta-stable phase diagram. This will provide the appearance of “unusual” metastable phases and certainly different microstructure in the final cast component.

The last, but not the least, is the influence of the processing environment. In many publications, and especially in the manufacturing practice, melting and casting are being done in “protective” or “inert” atmospheres. It is known that aluminum reacts with oxygen at very low partial pressures of the latter (at 750°C, the equilibrium oxygen pressure over Al is $\sim 4.4 \times 10^{-40}$ Pa). It is also clear that no furnace is capable of holding such low oxygen pressure, and thus, some small amount of aluminum oxide(s) will be always present in the system. These oxides may be rather stable even beyond 1200–1300°C, and may also act as crystallization nuclei. For example, for Al–20% Si alloy in alumina crucible, the equilibrium activity of dissolved oxygen will be ~ 25 times higher than in the same alloy, in the same atmosphere, but in a beryllia crucible.^[19]

ADVANCED TECHNIQUES FOR MICROSTRUCTURE MODIFICATIONS AND PROPERTY IMPROVEMENT FOR ALUMINUM ALLOYS

From the variety of aluminum alloys, one of the most important objects for studies on modification, grain size control, and property improvement is aluminum–silicon alloys. For the stable phase diagram, it is known that Al–Si eutectic, Al-rich (α), or Si-rich (β) phases are present in the system.^[6–9] Thus, modifiers or other additions should be selected on the basis of their target phase – modification of the primary silicon (β -phase) is obviously a different process than modification of the α -Al crystals. This foresees that α -, β -, and eutectic phases do always exist in the form prescribed by the phase diagram – in other words,

Table 6 Variation of experimental processing of Al–12% Si melts

Regime #	Temperature (°C)		Soaking time at T_{oh} (hr)	Cooling rate ($T_{oh} \rightarrow T_c$) (K/min)	DAS (μm)	Microhardness (MPa)
	Overheating (T_{oh})	Casting (T_c)				
1	800	800	5	–	40	700
2	800	700	5	4.2	35	710
3	1080	700	0.1	9	20	750
4	1090	700	0.1	9	15	900
5	1080	700	0.1 ^a	486	<10	1250

^aAdditionally soaked for 3hr at the casting temperature of 700°C and then rapidly cooled.

Authors^[19,25,28,33] have studied in detail possible metastable phase transformations and equilibria in the Al–Si system for realistic processing conditions. The starting point was that the Al–Si system is very similar to the Fe–C system (metal–non-metal, eutectic equilibrium), but formation of the metastable cementite Fe_3C in the latter is well known and easily realized.^[33] It was suggested that similar metastable phases do exist in the Al–Si system as well, but their stability may be of a few orders lower than that of cementite. In the 1970s the first metastable Al–Si phase (cubic X-phase, $a = 0.69891$ nm) was found in rapidly solidified thin films. Analysis of the Al–Si alloys with 6–40% Si has demonstrated such a variety of morphology of eutectic, α -, and β -phases as cannot be explained by simple eutectic crystallization.^[33] There, two other metastable phases (η , ω) have been found.^[28,33] In the near-eutectic region (10–12% Si), it was discovered that these phases also form metastable eutectics ($\eta + \text{X}$ and $\alpha + \omega$), and their composition depends on the overheating temperature. Iron impurities (up to 0.3%) were observed to stabilize these eutectics. Finally, additional phases have been found, and analyzed by X-ray diffraction and microanalysis in the Al–Si hypereutectic alloys^[19,25] (Table 7). These phases may stay for several minutes, weeks, or days and may be discovered by X-ray diffraction and transmission electron microscopy (TEM). For example, the tetragonal ψ -phase was found by TEM electron beam to fully decompose in 4 min, but in the Al–18.68% Si alloy with 0.05%

This phase diagram summarizes the discovered metastable phases, but it is necessary to note that appearance of the phases depends on the overheating temperature and soaking time at this temperature. Besides this, it was also found that the phase appearance sequence depends on the time for isothermal solidification.^[19,28] Isothermal solidification of the Al-21.5% Si alloy was studied by overheating synthetic melt to different temperatures for 30–40 min, transferring it to the thermostat made on the basis of Al-Cu-Si alloy (for 1–100 sec), and quenching.^[19,25] The resulting specimens were studied by different methods and phase stability areas, and their transformation kinetics were determined. As an example, Fig. 8 shows the phase formation sequence in the Al-21.5% Si alloy, overheated to 900°C, soaked for various times at different temperatures, and rapidly quenched. At ~700°C and ~750°C, the liquid remains stable for quite a long time, but the α -phase appears in the liquid after incubation for ~20 sec above 700°C and the ω -phase, below 700°C. Unlike for the melt overheated to 830°C, the α -phase does not turn into the ω -phase but disappears, forming liquid. At lower isothermal soakings, the ω -phase seems to be the first one, followed by the η -phase below 650°C. Approaching stable eutectic temperature (577°C), the phase change sequence gets more complicated, but after ~100 sec of soaking, only α - and β - phases remain in the structure. It is important that after decomposition of the metastable phases, only silicon crystals and the eutectic will appear in the

Phase name	Structural type and parameters (nm)	Silicon content (at. %)	Possible formula
X	Cubic, $a = 0.69891$	7.0–8.5	Al_6Si
η	Rhombohedral, $a = 0.74770$, $b = 0.7663$, $c = 0.5759$	15–18	Al_4Si
ω	Hexagonal, $a = 0.50597$, $c = 1.10225$	29–32	Al_7Si_3
$\text{\ae}$	Tetragonal, $a = 0.3695$, $c = 0.7160$	37.5–38.5	$\text{Al}_{62}\text{Si}_{38}$
ψ	Tetragonal, $a = 0.4500$, $c = 0.8199$	42–45	Al_3Si_2
ρ	Tetragonal, $a = 0.4487$, $c = 0.5160$	51–52	AlSi

Fig. 7 Experimentally found metastable phases in the Al-Si system and their estimated phase diagram

Fig. 8 Formation of the metastable and stable phases in the Al-21.5% Si alloy overheated to 900°C and isothermally cooled at different temperatures

microstructure, but they will have different morphology and properties due to the various ways of metastable phase transformation.^[19,28] Eutectic $\alpha + (\text{Al, Si, Fe})$ is known to make alloys brittle, and thus, ways of stabilization of the ω -phase should be sought (here (Al, Si, Fe) means an iron-containing intermediate phase, the composition of which is not yet exactly known). This is an important measure for recycled Al-Si alloys with increased iron content.

The influence of iron additions on changes of the isothermal crystallization was also studied^[28] (Fig. 9). In the Al-21.5% Si-2% Fe alloy, preheated at 830°C, during such crystallization, the starting liquid between 3 and 40 sec transforms to:

700–750°C	the stable liquid
680–700°C	liquid + ω
590–680°C	liquid + $\omega \rightarrow$ liquid + $\omega + \eta$
570–580°C	liquid of increased stability $\rightarrow$ liquid + $\omega \rightarrow$ liquid + $\omega + \eta$
530–560°C	liquid + $\omega + \eta + \rightarrow$ liquid + $\eta + (\omega + \eta)_{\text{eutectic}}$

In comparison with non-alloyed Al-Si melt, iron additions decrease the incubation time for ω -phase formation and increase its stability area. In the case of oxygen additions (Al-21.5% Si-2% O) (Fig. 10), the starting liquid has the following transformations:^[28]

730–750°C	the stable liquid
590–720°C	liquid + η
570–580°C	liquid of increased stability $\rightarrow$ liquid + η
530–560°C	liquid + $\eta \rightarrow$ liquid + $\eta + \alpha + (\alpha + \eta)_{\text{eutectic}} \rightarrow$ liquid + $\eta + \alpha + (\alpha + \beta)_{\text{eutectic}} \rightarrow \alpha + \beta +$ $(\alpha + \beta)_{\text{eutectic}} + (\alpha + (\text{Al, Si, Fe}))_{\text{eutectic}}$

Fig. 9 Isothermal crystallization of the Al-21.5% Si-2% Fe alloy, preheated at 830°C: 1 – liquid + $\omega + \eta$, 2 – liquid + ω , 3 – $\alpha + \beta + (\alpha + \beta)_{\text{eutectic}} + (\alpha + (\text{Al, Si, Fe}))_{\text{eutectic}}$. Dashed lines are phase areas of unalloyed Al-21.5% Si alloy, as shown in Fig. 8

Fig. 10 Isothermal crystallization of the Al-21.5% Si-2% O alloy, preheated at 830°C: 1 – liquid + η , 3 – $\alpha + \beta + (\alpha + \beta)_{\text{eutectic}} + (\alpha + (\text{Al, Si, Fe}))_{\text{eutectic}}$ (note that the stability area of “liquid + ω ” is greatly suppressed). Dashed lines are phase areas of unalloyed Al-21.5% Si alloy, as shown in Fig. 8

Here, it is seen that oxygen suppresses formation of the ω -phase formation and promotes formation of the more brittle $(\alpha + (\text{Al, Si, Fe}))_{\text{eutectic}}$.

Comparison between microstructures of Al-Si alloys with and without oxygen and iron additions has shown significant differences in eutectic fractions and crystal morphology (cross-sectional area variation is 8–10 times). Metastable phases, which do form first during the crystallization, have always some amount of stabilizing additions (impurities) hindering their decomposition. For instance, the Z-phase (Al_4Si) may contain substantial amounts of oxygen,^[19,25] and its lattice parameters are close to those of the sillimanite Al_2SiO_5 . Also, the hexagonal lattice of the ω -phase is isomorphic to the intermetallide $\text{Al}_{12}\text{Fe}_3\text{Si}_2$,^[9,25] and the ω -phase may thus be stabilized by iron additions. The lifetime of these phases under other equal conditions

Fig. 11 Shape and morphology of the silicon crystals in the Al–Si alloy. White squares indicate approximate places for the photos on the right

depends on the oxygen and iron concentrations in the alloy. That is why recognition of these metastable phases in pure Al–Si alloys is very difficult, due to their fast transformation into various forms of silicon and eutectics.

A. V. Mazur has studied the morphology of silicon crystals in the Al–Si alloys and revealed some peculiarities of their shape and surface correlation with practical properties of Al–Si castings.^[19] It was found that special physical–chemical treatment (patent pending) of the Al–12% Si–2% Cu–1% Mg–1% Ni melt leads to certain transformations in silicon crystal growth and in its shape (Fig. 11). The silicon shape changes have led to simultaneous increase of both the strength and the ductility of the Al–Si alloy, which has led to a significant improvement in diesel engine piston quality.

Similar data for metastable phase formation and their influence on properties were obtained for hypoeutectic Al–Si
